Present-day Techniques

USE OF BISACODYL IN PREPARATION OF THE BOWELS FOR A BARIUM ENEMA

BY

J. G. SOWERBUTTS

From the Radiodiagnostic Department, the London Hospital

This account of a new and successful technique in preparing patients for a barium enema examination will interest clinicians, for its eventual adoption by radiologists would greatly reduce the discomfort of this invaluable but disagreeable investigation.

Half a century has elapsed since Rieder (1904) and Schüle (1904) first reported the use of opaque media for radiographic examination of the colon, during which time many other techniques have been improved. At the same time, whether due to medical prejudice or to the assertion of an exclusive nursing prerogative over the patient's bowels, methods of preparing the colon for the injection of barium do not appear to have shared in this process of general refinement. Nevertheless, a useful outcome from barium enema examination depends in no small measure upon this neglected aspect of technique.

Haenisch (1911) gave the first full review of the subject, and his exhaustive account includes the statement that "thorough cleansing of the intestine by giving purgatives and cleansing enema is highly essential". Methods in general would appear to have changed little since his day. Various authorities (Sante, 1956; Storch, 1957) recommend a variety of measures, starting with dietary restriction of considerable austerity, and leading, via purgation with castor oil or phenolphthalein, to the administration of enema of normal saline, soap and water, or, where gas is excessive, of ox bile and turpentine. Alternatively, plain water washouts may be given at half-hourly intervals until the fluid is returned clean. According to a standard British textbook (Shanks, 1958), the only satisfactory method of giving it is by means of the Studa chair in which 30-50 pints of fluid may have to be used before the return is clear.

Because the absence of an agreed standardized procedure makes it impossible to generalize, it is probable that the practice in most radiodiagnostic departments in this country closely resembles our own in relying largely on enemas and colonic lavage.

It was not until 1953 that a practical alternative to these methods became available. In that year the German pharmacologist Schmidt (1953) reported the synthesis of a new laxative substance now known as bisacodyl ("dulcolax"). This substance is not absorbed from the gut and is strikingly free from toxicity. Its presence within the lumen of the bowel initiates normal peristalsis due to direct contact with the mucosa, acting possibly through the local nerve plexuses. Clinical reports from Germany (Stockmeier, 1953; Frankl, 1953) confirmed its effectiveness in a variety of forms of constipation, and, since its widespread adoption in Britain, reports have appeared of its use in general medical and surgical cases (Church, 1959; Rutter, 1959) and in chronic sick and geriatric patients (Clark, 1957).

As a method of preparation for radiography, "dulcolax" suppositories were used by Hauff (1954) and Kolshorn (1954). The procedure used by these investigators consisted of either "dulcolax" tablets or a suppository on the evening before examination, and one suppository on the morning of examination, satisfactory bowel clearances being reported. Keogh and Fraser (1958) compared the effectiveness of bowel preparation in 100 patients prepared with castor oil and a cleansing enema and 142 patients given "dulcolax", and found that the "dulcolax" series gave better results. Good results were also obtained in a larger series of 249 patients prepared with bisacodyl (Poppel and Bangappa, 1959).

METHOD OF INVESTIGATION

In order to establish that it was possible to dispense with the enema and lavage commonly used in preparation for the barium enema, a "blind" enquiry was started in
this hospital in which the radiologists had to report on
the adequacy of preparation at the time they read the
films, without knowing what form of preparation had
been used.

With the consent and cooperation of a number of
medical and surgical consultants, patients referred for
barium enema examination were allocated either to
“old” or to “new” groups. Patients were allocated largely
on the basis of the referring consultant, the ward sister
being told that Mr. A’s patients were to be given the
“old” preparation and Dr. B’s the “new”, the method
being such that no observable difference emerged in age,
nature or severity of illness, etc., between the two groups
of cases.

**"OLD" METHOD OF PREPARATION**

<table>
<thead>
<tr>
<th>Previous evening</th>
<th>One-and-a-half pint enema (4 oz. soft soap per pint) or disposable enema</th>
</tr>
</thead>
<tbody>
<tr>
<td>4 to 6 hr. before examination</td>
<td>Plain water lavage until clear</td>
</tr>
</tbody>
</table>

**"NEW" METHOD**

<table>
<thead>
<tr>
<th>Previous evening</th>
<th>&quot;Dulcolax&quot;, 10 mg. (2 tabs.) by mouth</th>
</tr>
</thead>
<tbody>
<tr>
<td>6 a.m. to 7 a.m. on morning before examination</td>
<td>One &quot;dulcolax&quot; suppository</td>
</tr>
<tr>
<td>One hour before examination</td>
<td>One &quot;dulcolax&quot; suppository</td>
</tr>
</tbody>
</table>

As a rule the examination took place either at 11 a.m.
or 1:30 p.m.

A note of the method used was made by the ward
sister but did not appear on the form requesting a barium
enema. When he had read the films the radiologist
consulted was asked to complete a pro-forma stating
whether preparation was “satisfactory” or “unsatisfac-
tory”, and, if the latter, for what reason and whether
a diagnosis was still possible. The criteria used were as
follows:—

**Unsatisfactory**

Faecal matter present in gross amount throughout
colon, or failure to retain the enema

**Satisfactory**

Either empty of faeces, or faeces present in small
amount insufficient to interfere with making a
diagnosis

I was aware of the preparation used in each case but
was not concerned with giving the initial opinion on the
films. When the examination was over, the method of
preparation used was entered on a pro-forma.

Two hundred cases were reviewed in this manner,
100 being given the “old” preparation and 100 the
“new”. The patients, who were all in-patients, included
both sexes and all ages from 10 to 82 years. The majority
were under investigation for suspected neoplasm or
inflammatory lesions of the large bowel. Results are
given in the accompanying table. Analysis showed that
unsatisfactory results by either method bore no relation
to age, sex, or to the ward which was preparing the
enema. The patients marked “satisfactory” were later
graded into “good” where there was no faecal residue at
all in the colon, and “satisfactory” where minimal
faecal matter was present in one segment of the colon only.

Side-effects in the “dulcolax” series were never serious
but an occasional patient complained of colicky pain,
nausea, or a burning sensation in the rectum after the
suppository had been inserted. Our experience is that
two tablets give an adequate result and a higher dose is
inadvisable, particularly in the older age groups.

The relative lack of side-effects and the ease with
which “dulcolax” is given make this preparation very
suitable for the out-patient barium enema examination.
Since the present series was completed many patients
having a barium enema have been satisfactorily examined
in this way.

**DISCUSSION**

The use of enemata and colonic lavage as a means
of preparation for barium enema carries with it a
number of disadvantages. In a proportion of cases
the colon is not cleared or only partly so and residual
gas or faeces may be troublesome. If the procedure
is not carried out a sufficient length of time before
the examination, droplets of fluid remaining in the
colon may obscure the mucosal pattern, or the
bowl may be irritated by the agents employed.
A further important drawback is the risk of water
intoxication to which attention has recently been
drawn (Lancet, 1959). It is known that in sus-
cetable cases absorption of hypotonic fluid can lead
to neurological disturbances (Hiatt, 1951). Although
most reported instances are in cases of megacolon,
Ziskind and Gellis (1958) have shown that even in
cases with a normal colon the volume of fluid
returned after colonic lavage amounts to only
10 to 50% of that injected. When it is remembered
that the procedure may involve the injection and
return of 20 to 30 pints of water over the course of
several hours, it becomes clear that an element of
risk undoubtedly exists. Moreover, when the impact
upon the patient, both physically and psychologic-
ally, of this “onslaught by water” is taken into
account, many would doubt whether it can be
justified at all except in the presence of clear and
unequivocal indications.

Finally, the time expended by the nursing staff in
administering the enema and lavage (at least half an
hour), as well as in cleaning and maintaining the

</table>

*Since each group contained 100 patients, the figures may be read as percentages.*

---

**Note:**

Nursing staff involved in the preparation of enemas and
lavages should be aware of the potential risks and
side-effects associated with these procedures and take
appropriate measures to minimize them.
PRESENT-DAY TECHNIQUES

CONCLUSION
The features of the ideal method of bowel preparation may be enumerated as follows:—
(1) It should produce complete and consistent bowel emptying within a predictable period of time.
(2) After emptying, the bowel should be left in an otherwise unaltered condition.
(3) From the patients' point of view the period of preparation should be short and the method should cause neither discomfort nor apprehension.
(4) From the nurses' point of view the method should be simple and quick.
(5) From the radiologists' point of view the procedure should result in a clear, unobstructed field of vision.
(6) There should be no side-effects or complications.

The conclusion to be drawn from this enquiry is that bisacodyl is an effective substitute for traditional methods of preparing the bowel and has the additional advantages of being simpler and quicker to administer and of being less unpleasant for the patient.

In view of the increasing use in hospitals of disposable enemata, it may be of interest to mention the following relative costs:—

<table>
<thead>
<tr>
<th>Disposal enema</th>
<th>Basic Cost to N.H.S.</th>
</tr>

GASTRO-INTESTINAL BLOOD LOSS MEASURED BY RADIOACTIVE CHROMIUM

BY

A. D. CAMERON

From the Department of Gastroenterology, Central Middlesex Hospital, London

A new technique is described for the measurement of blood loss in the faeces of patients labelled with radioactive chromium (\(^{51}\text{Cr}\)). The method is simple and is probably more accurate at low levels of faecal radioactivity than those previously described. The method will measure as little as 0.02\(\mu\)C of \(^{51}\text{Cr}\) in whole blood in a 24-hour stool.

The apparent average daily blood loss in a series of 10 normal people averaged 0.6 ml., with a range of 0.3 to 1.3 ml.

Estimations of plasma and salivary radioactivity have been made in an attempt to assess the importance of contamination from eluted \(^{51}\text{Cr}\). Minor radioactivity in plasma but none in saliva was recorded. Stool contamination from such sources is thought to be insignificant.

No significant correlation existed between chemical occult blood tests and isotope measurements, where there was less than 10 ml. of whole blood in a 24-hour stool.
