Lactosylceramide in inflammatory bowel disease: a biochemical study

C R STEVENS, V G OBERHOLZER, J A WALKER-SMITH, AND A D PHILLIPS

From the Queen Elizabeth Hospital for Children, London

SUMMARY  A simple technique for isolating lipids from small pieces of tissue was applied to mucosal biopsies and samples of resected intestine from patients with inflammatory bowel disease. Scanning densitometry of two dimensional chromatograms showed increased concentrations of the membrane associated glycosphingolipid lactosylceramide in Crohn’s disease, on comparison with ulcerative colitis (p<0.01), or controls (p<0.01). This indicates either that normal glycosphingolipid metabolism is altered, or that a novel source of lactosylceramide is present in the inflamed mucosa of patients with Crohn’s disease.

A previous ultrastructural study from this hospital observed small round microvilli and desmosome associated bodies in small and large intestinal mucosal biopsies from patients with inflammatory bowel disease. Preliminary histochemical analysis, suggesting that they may be plasmalogen in nature (Lewis et al, unpublished observations), prompted chromatographic analysis of the lipid content of mucosal extracts from such patients. Initial work showed no abnormality in plasmalogens, however, another type of lipid, lactosylceramide, was found to be greatly increased in Crohn’s disease. This paper describes a preliminary visual assessment and a subsequent estimation by scanning densitometry of the presence of lactosylceramide in inflammatory bowel disease.

Methods

PATIENTS
A total of 65 patients (57 children, eight adults) were studied, 32 provided samples for an initial visual assessment of lipid content and 33 for an objective study using scanning densitometry. These were divided into four clinical categories as shown in the Table. Categorisation of the patients was achieved

using diagnoses made from a combination of clinical, radiological, endoscopic, and histological criteria. 

All patients were examined endoscopically to investigate clinical symptoms compatible with inflammatory bowel disease, and a provisional diagnosis could sometimes be made from the site and appearance of inflammation.

A final diagnosis is usually made from a histological examination of endoscopic biopsies. Positive stigmas of ulcerative colitis are mucosal crypt distortion and crypt abscesses, mucus depletion, and a uniformity of inflammation. The lesion in Crohn's disease, however, characteristically consists of patchy, focal inflammation, which may be transmural, with non-caseating granulomata in 40–70% of cases. The cases of indeterminate colitis have been impossible to categorise as either definite Crohn's disease or ulcerative colitis by the means outlined above.

Twenty two patients had Crohn's disease of which four had ileal disease only, two colonic disease only, and 16 had ileal and colonic disease. Three patients were adults. The ages of the children ranged from 8 years 8 months to 17 years 11 months, with a median age of 14 years 3 months. The medical records of 18 of these patients were available. Six patients were not receiving medication at the time of biopsy whereas 12 were receiving Salazopyrin and/or Prednisolone. Duration of disease ranged from one month to nine years with most patients studied two to four years after onset of symptoms. Eleven of 16 erythrocyte sedimentation rate (ESR) measurements before colonoscopy were abnormal (>20 mm/hour).

Sixteen of the 21 patients with ulcerative colitis were children with a median age of 13 years 1 month (range 6 years 2 months to 15 years 6 months). The medical records of 14 of these patients were available. Two patients were on Salazopyrin. Twelve patients were receiving Prednisolone and of these, five were also on Salazopyrin and three on Mesalazine. Antidiarrhoeal drugs were in use in four cases (three Loperamide, one Lomotil). Duration of disease ranged from 7 months to 10 years, and the majority of patients were studied one to four years after onset of symptoms. Five of nine ESR measurements taken before colonoscopy were above normal limits.

The three children with indeterminate colitis had ages of 12 years 2 months, 10 years 6 months and 9 years 2 months; their disease durations were four years, two years six months, and 10 months respectively. All three were receiving Prednisolone at the time of biopsy.

The control group consisted of 19 children (median age 8 years 2 months, range 11 months to 14 years) and one adult. All underwent colonoscopy to investi-
ml methanol/chloroform/water mixture (10:5:4) for four minutes in a hand homogeniser (Baird and Tatlock 10 mm diameter). A further 0-5 ml chloroform was added and homogenisation repeated for four minutes to enhance extraction. Distilled water, 0-5 ml, was added to separate the chloroform extract from the aqueous methanol phase. The resulting bilayer was clarified by centrifugation at 500 g for 10 minutes and the extract (lower phase) taken to dryness under a stream of nitrogen in a heated (37°C) block (Grant Instruments).

**TWO DIMENSIONAL THIN-LAYER CHROMATOGRAPHY (2D-TLC)**

Chromatographic sheets (10 cm x 10 cm Silica Gel G 60 plastic backed. Merck AG, no 5748 BDH) were heat activated at 80°C for at least one hour before sample application. Dried lipid extracts were redissolved in 25 μl chloroform and aliquots applied to one corner of each sheet. The total extract from small biopsy samples was applied whereas larger biopsies and pieces of resection supplied more than enough extract to give a clear chromatogram so that only fractions of the total extract were applied. Samples were first run in a solvent system of chloroform/methanol/toluene/water (70:35:25:5). On completion, and after drying in air, the sheets were turned through 90° and stood in an alkaline solvent system chloroform/methanol/toluene/5M aqueous ammonia (70:35:25:5). Lipid spots were visualised by charring the sheets in a fan assisted oven at 110°C ± 1°C, after dipping in 5M H2SO4/methanol (2:5). The chromatograms were examined on a light box immediately after charring.

**LIPID IDENTIFICATION**

The lipid spots seen on 2D-TLC were first categorised by their reaction with spray reagents – for example, molybdenum blue, which detects phospholipids, and orcinol and diphenylamine, which detect glycolipids. Further elucidation was achieved by comparing spot migration rates determined by TLC with previously observed values for known lipids. Finally, commercially available standards of the main phospholipids and glycolipids were obtained and individually cochromatographed with the extracted lipid fraction. The identity of each lipid was given as that of its comigrating standard after careful comparison of spot colour and mobility. A standard of lactosylceramide was not commercially available so a sample isolated from a patient with Crohn's disease was sent for confirmation of identity to Dr B A Machar, University of California, who in turn, kindly provided a positive standard.

Lipid spots were isolated for identification by scraping the appropriate area of silica gel from a chromatogram then eluting the resultant powdered silica with chloroform/methanol (2:1) dropwise through a syringe plugged with fine glass wool. The eluant was taken to dryness as before and stored at −20°C.

**QUALITATIVE ESTIMATION OF LACTOSYLCEERAMIDE**

A visual assessment of the two closely travelling purple-grey lactosylceramide spots was made as absent – that is, not visible, faintly present, and strongly present.

**ESTIMATION OF LACTOSYLCEERAMIDE BY SCANNING DENSITOMETRY**

Thirty three tissue samples (Table) were coded before extraction and chromatography as described above. Chromatograms were processed under constant conditions of temperature and timing to standardise the inherent variables of spot intensity, background, and degree of charring and fading. Values for the spot densities of lactosylceramide and phosphatidylethanolamine were obtained using a Joyce Loebl Chromoscan 3 densitometer (Joyce-Loebl, Gateshead, Tyne and Wear). The Chromoscan 3 is a high performance densitometer under microprocessor control (Intel 8085). The raster scan has a resolution of 5 μm. All chromatograms were scanned not more than three hours after charring at 530 nm wavelength, with absorbance set at 1, using a 1 mm2 aperture in raster mode.

The small amount of tissue available did not allow a measurement of lactosylceramide per weight of biopsy or weight of protein. Lactosylceramide (LC) was therefore expressed as a density ratio to that of a reference phospholipid present in the same extract. Phosphatidylethanolamine (PE) was chosen as the reference because it constitutes 30–35% of membrane phospholipid and exists in different tissues in comparable quantities. Assuming these statements to be valid for the lipid content of diseased and healthy intestinal mucosa, we considered the amount of phosphatidylethanolamine present on a chromatogram to represent the amount of tissue which provided the spotted extract. Phosphatidylethanolamine appeared in all the analysed extracts as a compact, well separated spot which travelled to a position unaffected by interference bands arising from impurities in the silica gel itself. These factors facilitated the accurate and reproducible measurement of phosphatidylethanolamine density by scanning densitometry.

To assess the reproducibility of the LC/PE ratio graded dilutions (1:1–1:30) of an extract from a patient with Crohn's disease were chromatographed and their densitometric data analysed. Also, equal
Lactosylceramide in inflammatory bowel disease: a biochemical study
 aliquots of homogeneous neutrophil samples from a normal adult donor were processed separately to assess the reproducibility of the extraction technique.

Statistical analysis of the results was performed using the Mann-Whitney U-test.

Results

Figure 1 illustrates representative examples of the results of lipid fractionation by 2D-TLC of normal mucosa, Crohn’s disease affected mucosa and mucosa affected by ulcerative colitis. Figure 1a shows the relative positions of the separated lipids in a representative sample from the control group. This pattern was consistently present in all patients, including those in the disease groups, as seen in Figures 1b and 1c. In addition, as indicated in Figure 1b, two spots appear strongly in the chromatograms of extracts from patients with Crohn’s disease. In ulcerative colitis these two spots were either not seen or were faintly present, as illustrated in Figure 1c. The relative position of travel of these spots on the chromatogram and their staining characteristics suggested a disaccharide ceramide (probably lactosylceramide). This was confirmed by Dr B A Macher who reported that a sample of this lipid eluted from a chromatogram of resected mucosa from a patient with Crohn’s disease, ‘clearly co-migrated’ with lactosylceramide which had been isolated from human neutrophils. A sample of purified lactosylceramide, supplied by Dr Macher, gave identical double spots on chromatography and co-migrated, in a range of solvent systems, with the two spots observed in Crohn’s disease.

Figure 1d illustrates a chromatogram of the lipid extract from approximately 18×10⁶ neutrophils isolated from normal human peripheral blood. Lactosylceramide can be seen to be ‘strongly present’ in the same relative position as that seen in Crohn’s disease (Fig. 1b).

Figure 2 shows the accumulated data from our initial study of 32 patients. Lactosylceramide was not detected in extracts from the control patients nor from two cases of ulcerative colitis. The majority of samples from patients with ulcerative colitis showed a ‘faintly present’ lactosylceramide double spot whereas in nine of the 10 cases of Crohn’s disease the double spot was ‘strongly present’. All samples from the terminal ileum in Crohn’s disease showed strongly present spots; the faintly present sample came from the left colon.

Lactosylceramide was not detected by chromatography of lipid extracts from uninvolved areas of the bowel in patients with Crohn’s disease nor from patients with coeliac disease nor from those cases with microscopic colitis.

The LC/PE ratio provided by scanning densitometry, was plotted for each of the 33 patients after breaking the code to determine the appropriate diagnostic category (Fig. 3). The LC/PE ratios (median 0.57, range 0.3–1.57) in patients with
Lactosylceramide in inflammatory bowel disease: a biochemical study

Crohn’s disease were significantly higher than the ratios (median 0.18, range 0.04–0.41) in patients with ulcerative colitis (p<0.01). The ratios in the control patients (median 0.08, range 0.01–0.12) were significantly lower than those of Crohn’s disease (p<0.01) and ulcerative colitis (p=0.05). The three lowest results in the Crohn’s disease group were from colonic biopsies. The single rectal sample gave a LC/PE ratio of 1.15.

The values for the three patients with an indeterminate colitis (0.94, 0.32, and 0.22) are also indicated in Figure 3.

Medication and ESR at time of biopsy or surgery bore no obvious relationship to the pattern of the results, neither did disease duration.

Lactosylceramide/phosphatidylethanolamine ratio values were reproducible to between 98% and 102% of the mean value of five dilutions of the same extract. Phosphatidylethanolamine and lactosylceramide densitometer values increased in direct proportion to increasing extract concentration and to increasing volume of extract applied. Separate processing of equal aliquots of the same homogeneous sample of neutrophils resulted in lactosylceramide and phosphatidylethanolamine values which fell in a range between 94% and 106% of the mean value.

Discussion

Lipid analysis of mucosal extracts from patients with inflammatory bowel disease unexpectedly showed increased concentrations of twin spots on the lipid chromatogram in Crohn’s disease. The double spot appeared to be identical to that produced by the glycosphingolipid lactosylceramide and this was confirmed by comparison with the purified compound supplied by Dr Macher. A quantitative measurement of the lactosylceramide when expressed as a ratio to phosphatidylethanolamine gave significantly higher values for patients diagnosed as Crohn’s disease when compared with a group diagnosed as ulcerative colitis and to a control group.

In this study active disease sites were chosen for analysis. No patients with ulcerative colitis had active disease in the ileal region, in contrast with patients with Crohn’s disease, and so such areas were not studied. It is unlikely that uninvolved terminal ileum in ulcerative colitis would show increased lactosylceramide concentrations although it would be of interest to study cases of definite ulcerative colitis which show inflammation in the ileal region. There is a suggestion that lactosylceramide concentrations in Crohn’s disease may be lower in the colon than in the terminal ileum and rectum, although numbers are small.

The technique used provided a reproducible system for lipid analysis on small amounts of tissue and the use of an internal ratio to express lactosylceramide levels minimised processing variables between samples since in any one extract, as phosphatidylethanolamine and lactosylceramide should be subject to the same errors. Good reproducibility was shown using lipid extracts from blood neutrophil samples but it was not possible to investigate the variation of lactosylceramide measurements from the inflamed mucosa of individuals with inflammatory bowel disease because of the limits of tissue availability. We would predict some degree of variability between samples from patients with Crohn’s disease, however, because of the associated patchy nature of inflammation. This would tend to produce lower, rather than higher, concentrations of lactosylceramide and therefore reduce the difference between ulcerative colitis and Crohn’s disease.

Glycosphingolipids are a chemically well defined class of membrane molecules, the majority of which occupy and confer rigidity to the outer bilayer of plasma membranes, regulating membrane fluidity, membrane receptor protein function, and cell adhesion. Lactosylceramide is involved in the metabolism of the more complex glycosphingolipids and is present in low concentrations in normal areas of colon from adults with adenocarcinoma and normal rat small intestine. It is a simple glycosphingolipid having glucose and galactose in glycosidic linkage with a long chain aliphatic amine base coupled to fatty acid chains of variable length and appears as two spots on the chromatogram because the fatty acid chains exist mainly as two lengths, C16 to C18 and as C22 to C24. The lactosylceramide complement of a specific tissue is made up of a characteristic mixture of slightly differing ‘lactosylceramides’ although such differences may not be apparent on chromatography. In this study lactosylceramide could not be detected in the mucosa of control patients by visual means but low measurements were obtained using scanning densitometry. It would appear that in Crohn’s disease either a novel source of lactosylceramide is present in the mucosa or normal glycosphingolipid metabolism has been altered.

Lactosylceramide has been reported to be increased in a range of other disorders including Niemann-Pick disease type C, familial hypercholesterolemia, human colonic adenocarcinoma and other tumours, and virally transformed cell lines.

In Niemann-Pick disease type C there is a marked decrease in lysosomal lactosylceramide galactosyl hydrolase activity resulting in lactosylceramide accumulation in hepatocytes and macrophages. Further biochemical analysis is required to investi-
gate the possibility of a similar, but local, aberration in Crohn’s disease. Serum cholesterol concentrations are lower in Crohn’s disease than in normal subjects indicating no direct relationship between serum cholesterol and lactosylceramide concentrations. There was no evidence of adenocarcinoma in any of the patients studied and the observation that there is an increased risk of developing cancer in Crohn’s disease may not be relevant as a similar risk is described in ulcerative colitis and the increased concentration of lactosylceramide is described after, not before, carcinoma development. It has often been postulated that Crohn’s disease has an infective aetiology but to connect the increased lactosylceramide concentration with a possible viral cause would be premature in the absence of additional evidence.

A difference between the previously described examples of raised lactosylceramide concentrations and Crohn’s disease is that none of the former involve an inflammatory process. Neutrophils contain high concentrations of lactosylceramide and thus acutely inflamed tissue should show higher levels of lactosylceramide than non-inflamed tissue. Inflamed areas in Crohn’s disease were indeed found to contain higher amounts of lactosylceramide than non-inflamed regions, and this might be explained by the concentration of infiltrating neutrophils. There should therefore be significantly more neutrophils in Crohn’s disease than ulcerative colitis, however, if they are the source of the increase in lactosylceramide. Current evidence suggests that neutrophils are involved to a similar extent in both diseases, but objective quantitative data of mucosal neutrophil density is required to confirm this.

The reason for the increase in lactosylceramide is thus unclear, but it does offer some discrimination between ulcerative colitis and Crohn’s disease. A wide range of disease controls are required to establish if other conditions, for example, adenocarcinoma and infective colitides, show raised lactosylceramide concentrations, however, as mucosal tissue is required for the test, histological examination with its range of differential diagnoses remains the method of choice. Lactosylceramide measurement may be useful in the diagnosis of indeterminate colitis, where histology cannot make a clear distinction between Crohn’s disease and ulcerative colitis. The lactosylceramide to phosphatidylethanolamine ratio measurement produced an overlap between the two diseases, and one case of indeterminate colitis fell within this range. The other two cases gave probable diagnoses of Crohn’s disease and ulcerative colitis respectively. It remains to be seen if these predicted diagnoses are correct. Lactosylceramide measurement may be of more general use if the mucosal results are paralleled in samples of urine and/or faeces as it may then act as a simple screening test.

This work was funded by the Crohn’s in Childhood Research Appeal (CICRA). We would like to thank Miss Jane Sandall and the Imperial Cancer Research Fund, Lincoln Inn’s Field, for supplying scanning densitometry facilities. We also thank surgical and gastroenterological colleagues at St Bartholomew’s Hospital for providing tissue samples. Part of this work was published in abstract form in Gut 1985; 26: A1156.
