Prospective comparative study of the influence of postoperative bile reflux on gastric mucosal histology and *Campylobacter pylori* infection

From the Departments of Gastroenterology-Hepatology and Pathology, University Hospital Leiden and the Department of Surgery, Canisius-Wilhelmina Hospital, Nijmegen, The Netherlands

**SUMMARY** Biopsies of 17 peptic ulcer patients, randomly treated by partial gastrectomy with either Billroth-II (n=9) or Roux-en-Y (n=8) anastomosis were studied before and six months after surgery to determine the role of bile reflux in the early postoperative histological alterations of the gastric mucosa. After BII-gastrectomy bile acid reflux (median 16·1 μmol/h) was significantly higher (p<0·0001) than after RY-gastrectomy (0·1 μmol/h). *Campylobacter pylori* was present in the preoperative biopsies of all 17 patients. After RY-gastrectomy biopsies of all eight patients were positive for *Campylobacter pylori*, but was detected in only five of the nine patients with BII-gastrectomy. Preoperative scores of gastritis grading were similar in both groups and no significant differences were found postoperatively. Gastritis scores of the anastomotic mucosa in patients with BII-gastrectomy were significantly higher (p<0·02) than in the RY-gastrectomy group. Moreover, the reflux gastritis score in the four BII-gastrectomy patients cleared from *Campylobacter pylori* was significantly higher (p<0·02) than in the postgastrectomy patients harbouring *Campylobacter pylori*. The results suggest that reflux gastritis and *Campylobacter pylori* related gastritis are distinct microscopic entities and that bile reflux may play a role in the eradication of *Campylobacter pylori* after gastrectomy.

The gastric mucosa is repeatedly exposed to injurious agents of several kinds. Among others, postoperative reflux of bile is considered a factor of importance in the development of non-autoimmune chronic gastritis, the so-called postoperative alkaline gastritis. Recent observations show that the gastric mucosa frequently harbours *Campylobacter pylori*, suggesting that non-autoimmune gastritis in some instances may also be an infectious disease. In fact, about 90% of peptic ulcer patients have active gastritis and infection of the gastric mucosa with *Campylobacter pylori*. Especially the discovery of *Campylobacter pylori* as a potential pathogenic microorganism for the human gastric mucosa led to renewed interest in the different forms of gastritis and attempts to delineate their morphological features.

Some recent reports point to specific histological characteristics of reflux gastritis, which differ from *Campylobacter pylori* related gastritis. *Campylobacter pylori* related gastritis appears to be closely associated with chronic active gastritis, indicated by the presence of mono- and polymorphonuclear leucocytes. Delineation of the various morphological features, however, is almost always based upon retrospective examination of histopathological specimens with obvious drawbacks to define a histopathological entity. Moreover, the dynamics and evolution of inflammatory lesions in the postoperative gastric mucosa over time are well documented. Most study populations comprise nevertheless patients with postoperative intervals ranging from several months to several decades.

The purpose of our study therefore was prospect-
Prospective comparative study of the influence of postoperative bile reflux on gastric mucosal histology

**Methods**

**Patients**

Seventeen patients with peptic ulcer disease, not adequately responding to medical therapy, underwent elective gastrectomy. In all patients a two-thirds distal gastrectomy was performed and in random order a primary Roux-en-Y diversion or Billroth-II anastomosis was constructed. Nine patients underwent a partial gastrectomy with Billroth-II and eight patients a partial gastrectomy with Roux-en-Y anastomosis. Both groups were comparable with respect to mean age (52 vs 47 yr), sex (seven men and two women vs five men and three women) and indication for surgery (seven duodenal ulcer and two gastric ulcer vs six duodenal ulcer and two gastric ulcer). In the four gastric ulcer patients the ulcer was located at the angulus of the lesser curvature of the stomach. All patients were moderate to heavy smokers (10–20 cigarettes a day) at the time of operation. Six patients in the Billroth-II group and five in the Roux-en-Y group used moderate amounts (<80 g/day) of alcohol while none was treated by any medication at the time of the study. All the patients gave their informed consent to the study with pre- and postoperative endoscopy plus multiple gastric biopsies and quantitation of bile salts in the gastric aspirates. Endoscopies were performed one week preoperatively and six months postoperatively. The studies were approved by the local ethical committee on experimental investigations in man.

**Sampling Technique and Laboratory Methods**

After overnight fasting the patients underwent oesophagogastroduodenoscopy using the Olympus GIF-K fibre endoscope. At a separate occasion a nasogastric tube was installed intragastrically for measurement of reflux of bile salts for 60 min. The gastric aspirates were divided into four 15 minute samples. After measurement of the volumes, the concentrations of bile salts were determined using the Enzabile test kit (Nygard, Diagnostics Division Oslo, Norway). Fasting bile salt reflux was calculated for one hour, expressed as µmol/h.

Biopsy specimens were obtained using a forceps with spike and fenestrated cups. In each patient four biopsy specimens were taken preoperatively from the greater curvature of the antrum 5 cm from the pylorus and 4 cm from the corpus/fundus, two from the lesser curvature 5 cm distal from the cardia, and two from the greater curvature about half way cardiac-pylorus. Postoperatively, four stomal biopsies and four biopsies were obtained from the gastric remnant at similar sites as preoperatively. The biopsy specimens were orientated, immediately fixed in buffered formalin, and embedded in paraffin.

**Histological Assessment of Biopsy Specimens**

Paraffin processed 4 micron sections were cut at different levels, stained by haematoxylin and eosin, and an additional section from each biopsy was stained by the Warthin Starry method for *Campylobacter pylori.*

The sections were examined by one of us (GJAO), who was unaware of the operative procedure. The biopsies of antrum, lesser and greater curvature of corpus/fundus, and anastomosis were analysed separately. The activity and degree of gastritis at the various sites pre- and postoperatively were graded as nil (0), mild (1), moderate (2), and severe (3) by (a) the degree of polymorphonuclear infiltration and (b) the degree of infiltration by chronic inflammatory cells and the severity of mucosal degeneration according to Whitehead et al. The most severe alteration in a section, formed the score for that specific variable at that site. The scores for the two variables were added, giving a maximum gastritis activity score of 6. The specimens were also graded by the reflux gastritis score of Dixon et al. from absent (0) to severe (3), for the following features: (a) foveolar hyperplasia, (b) oedema and smooth muscle fibres in the lamina propria, (c) vasodilatation and congestion of the lamina propria, and paucity of (d) acute and (e) chronic inflammatory cells. The highest score in a section for a certain variable was again considered representative for that specific variable at that biopsy site. A composite reflux gastritis score was calculated for each patient by adding the scores allotted for each of the individual variables (minimum score 0, maximum score 15). The sections stained by the Warthin Starry method were examined for the presence of *Campylobacter pylori.*

**Statistical Analysis**

Results were expressed as median and range. Statistical analysis was done by Wilcoxon's rank-sum test. Differences in the prevalence of *Campylobacter*
*pylori* between the groups were tested for significance by the χ² test.

**Results**

**Bile reflux**

Preoperative fasting bile salts in the gastric aspirates of the patients who ultimately underwent a Billroth-II partial gastrectomy (median 0.35 μmol/h, range 0.05–4.60 μmol/h) were not significantly different from preoperative fasting bile salts in the patients who underwent a Roux-en-Y diversion (median 0.30 μmol/h, range 0.00–4.00 μmol/h). Postoperatively the fasting bile salt reflux was significantly higher (p<0.0001) after Billroth-II gastrectomy (median 16.10 μmol/h, range 0.01–779.27 μmol/h) than after Roux-en-Y gastrectomy (median 0.10 μmol/h, range 0.00–0.31 μmol/h).

**Histological assessment of the biopsy specimens**

**Gastritis activity score**

Table 1 shows the preoperative morphology of antrum and corpus graded according to Whitehead et al.² The microscopic picture was similar in patients who underwent BI1-gastrectomy as compared with the patients who ultimately underwent Roux-en-Y diversion. Postoperatively, no statistically significant differences were found between the two groups, although the polymorphonuclear infiltration at the Billroth-II anastomosis was slightly less than in the Roux-en-Y patients. In addition, there were no significant differences between the results of pre and postoperative biopsies.

**Reflex gastritis score**

Table 2 shows the results of the reflex gastritis score as graded according to Dixon et al.³ The preoperative scores were not significantly different. Postoperatively, no significant differences were found for the greater and lesser curvature of the body of the stomach, although the score tended to be higher after Billroth-II gastrectomy. The characteristics of reflex gastritis, however, were more pronounced in the Billroth-II anastomosis than in the Roux-en-Y anastomosis and the composite reflex score in the Billroth-II group was significantly (p<0.02) higher than in the Roux-en-Y group.

**Presence of Campylobacter pylori**

*Campylobacter pylori* was present in the preoperative mucosal biopsies of all 17 patients. After Roux-en-Y gastrectomy biopsies of all eight patients were still positive for *Campylobacter pylori*, whereas the microorganism was demonstrable in only five of the nine patients treated by a Billroth-II gastrectomy (p=0.06, χ² test). The four patients with Billroth-II gastrectomy whose mucosa was cleared from *Campylobacter pylori* had not been treated by antibiotics or colloidal bismuth in the period between the two endoscopies. Interestingly, both gastric ulcer patients who underwent gastrectomy with Billroth-II anastomosis were free of *Campylobacter pylori* in the postoperative biopsies. As shown in Figure 1, the reflex gastritis score was significantly (p<0.02) higher in the four *Campylobacter pylori* negative patients as compared with the 13 *Campylobacter pylori* positive patients. The results of the gastric ulcer patients were not different from the patients operated upon for duodenal ulcer. In contrast, the gastritis activity score as shown in Figure 2, was significantly higher (p<0.02) in the 13 *Campylobacter pylori* positive patients than in the four

Prospective comparative study of the influence of postoperative bile reflux on gastric mucosal histology

that bile reflux depends on the surgical procedure and the type of reconstruction performed after gastrectomy. The effect of diversion of bile on the histopathology of the gastric mucosa is more controversial. Surgical measures which proved to reduce bile reflux failed to show a difference for the histopathological picture of gastritis, making it questionable whether or not reflux of bile influences the architecture of the gastric mucosa at all. The poor correlation between histology and bile reflux could be partly explained by the fact that in all studies selected symptomatic patients with previous gastric surgery subsequently underwent a Roux-en-Y diversion. Furthermore, comparison of the degree of gastritis is almost without exception based on grades of chronic gastritis and inflammatory cell infiltration. Dixon et al recently postulated that reflux of bile is associated with a distinctive histopathological entity in which foveolar hyperplasia, vasodilatation, interstitial oedema and congestion, and paucity of inflammatory cells are the hallmarks. Foveolar hyperplasia as a characteristic of alkaline reflux gastritis has been emphasised by others and

Discussion

Elimination of bile reflux by diversion of bile through a Roux-en-Y construction in patients with reflux gastritis is well documented. Our study confirms

patients whose gastric mucosa was cleared from the microorganism.

one of these reports also points to the relative absence of inflammatory cells. It has to be stressed, however, that reflux gastritis is not a unique histological entity, as similar features can be seen in the neighbouring mucosa of chronic erosions, foveolar and hyperplastic polyps, Ménétrier’s disease or gastritis cystica profunda. These conditions, however, were not present in the patients studied.

Redness and swelling of the gastric mucosa in reflux gastritis are well known macroscopic features for the clinician during endoscopy. The microscopic analogues (hyperaemia, congestion, vaso-dilatation and oedema), may have been too little appreciated by histopathologists until now.

Recognition of alkaline reflux gastritis as a separate microscopic picture has obvious clinical significance. When definition of this picture, however, is based on retrospective examination of histopathological material from outpatient departments or hospitals, it may be biased and not representative for alkaline reflux gastritis in general. Furthermore, the evolution of inflammatory changes and the development of the histopathological features of postoperative reflux gastritis as a function of time should be taken into account. In most studies the intervals from the initial surgery show wide variations and no subdivision according to length of postoperative interval has been made, thus ignoring the dynamic principles of the behaviour of gastritis.

The present study is, to our knowledge, the first randomised trial in which prospectively the influence of bile reflux on the human gastric mucosa was investigated. It confirms that, at least in the early postoperative stage, gastritis at the site of the anastomosis after Billroth-II resection seems to be characterised by specific features as recently recapitulated by Dixon et al. For the body of the gastric remnant the higher reflux gastritis scores after Billroth-II resection failed to reach statistical significance when compared with biopsies from the respective sites preoperatively and after Roux-en-Y diversion. The finding that the reflux activity score at the anastomosis was increased, while the gastritis activity score was not affected by Billroth-II gastrectomy may seem to be contradictory, because infiltration of the gastric mucosa with inflammatory cells is a feature contributing oppositely to the scores of both classifications. The gastritis score according to Whitehead, however, depends heavily on infiltration with inflammatory cells, whereas paucity of these cells in the gastric mucosa contributes only for 40% to the reflux activity score. Thus, the increase in reflux score was mainly caused by other factors, such as foveolar hyperplasia, oedema and vasodilatation. Furthermore, there was in fact a weak tendency to a decreased density of inflammatory cells postopera-
