SUMMARY The efficacy of ranitidine (150 mg nocte), and sucralfate (1 g tds) as maintenance therapy to prevent gastric ulcer relapse was evaluated in a 12 month trial in 363 patients. The relapse rates were 8.8% at three months, 14.7% at six months, 18.1% at nine months, and 21.0% at 12 months for the ranitidine group and 14.7%, 21.3%, 29.9%, and 30.2% respectively for the sucralfate group. At nine and 12 months the cumulative relapse rates for the ranitidine group were significantly lower than those for the sucralfate group (p<0.05). In both groups ulcers recurred mainly from red scars observed at the endoscopic scarring stage. This indicated the necessity of drug treatment up to the white scar stage. The results suggest that ranitidine is effective in preventing gastric ulcer relapse.

Gastric acid is generally considered to be a key factor in peptic ulcer development and the histamine H2 receptor blockers which inhibit its formation have become standard therapy for treatment of both duodenal and gastric ulcer.

On average duodenal ulcer patients secrete more gastric acid than healthy control subjects. Many clinical trials have therefore been conducted with H2 blockers to evaluate their use as to prevent duodenal ulcer relapse.1-4

In contrast gastric ulcer patients as a group secrete less acid than normal and are usually considered to have an imbalance between agressive and defensive factors resulting from impaired gastric defence.

This imbalance may, in theory, be rectified by therapeutic intervention which acts to increase mucosal defence or to inhibit gastric acid and pepsin. As there is no definitive information on the relative merits of these two approaches to treatment we have conducted a large clinical trial to compare the effects of ranitidine, an agent which inhibits gastric acid secretion and sucralfate, a mucosal protective agent in the prevention of gastric ulcer relapse.

Methods

Patients Patients whose gastric ulcers had healed after any active treatment were recruited if endoscopy had confirmed the ulcer and its healing and if they were suitable for outpatient management.

Dosage and Administration The effects of ranitidine (Glaxo, UK), 150 mg/day at bedtime, and sucralfate (Chugai Pharmaceutical Co, Japan), 1 g tds, on the rate of gastric ulcer relapse were compared in a one year maintenance trial conducted by investigators in 72 centres.

Each patient received either four 250 mg tablets of sucralfate three times a day (before breakfast and lunch and at bedtime) or four placebo tablets before breakfast and lunch and one 150 mg ranitidine tablet with three placebo tablets at bedtime. In order to maintain blindness, all the drugs and placebo tablets were prepared in packages which were indistinguishable in their appearance.

Trial Design Endoscopic examination of the stomach was performed on five occasions, that is, when healing was confirmed and at three, six, nine, and 12 months...
The background factors of the patients were compared by the \( \chi^2 \) test. For all of these statistical methods, \( p<0.005 \) was regarded as indicative of a significant difference.

**Results**

**Comparison of Subjects**

Three hundred and sixty-three patients with a healed gastric ulcer were randomised into two groups: 180 received ranitidine and 183 patients sucralfate. Seventeen subjects were excluded for the reasons presented in Table 1. Table 2 shows the demographic data for the remaining 346 subjects (171 received ranitidine and 175 sucralfate) who were eligible for

\[

\end{array}
\]

\text{*Others Gefarnate, Cetraxate, etc.}
Analysis, and no significant differences were noted for any of those factors. Previous ulcer treatment for the healing phase is shown in Table 3. In both drug groups many subjects had been treated with \( \mathrm{H}_2 \) receptor blockers but there was no difference in the distribution of any of the treatments. Also, in most cases in both groups, a red scar stage was detected at the initial endoscopic examination (Table 2).

**Cumulative Relapse Rates**

Table 4 shows the relapse status for the two treatment groups for each three month period of the study. The number of patients who had relapsed was 29 for ranitidine and 44 for sucralfate. In both treatment groups, ulcer relapse occurred most frequently during the first three month period: 14 cases for ranitidine and 24 cases for sucralfate. Figure 1 shows the cumulative relapse rates with both drugs calculated by Cutler-Ederer life table analysis. The cumulative relapse rates for ranitidine at three, six, nine, and 12 months were 8-8%, 14-7%, 18-1%, and 21-0%, while those for the sucralfate group were 14-7%, 21-3%, 29-9%, and 30-2% respectively. The cumulative relapse rates at nine and 12 months in the ranitidine group were significantly lower than those in the sucralfate group (\( p<0.05 \)). The symptomatic relapse rates at three and six months were 6-9% and 10-9% for the ranitidine group and 9-2% and 10-7% for sucralfate group. The differences between the groups were not statistically significant. The symptomatic relapse rates at nine and 12 months were 11-7% and 12-7% for ranitidine and 18-5% and 19-6% for sucralfate, however, suggesting more symptomatic relapse with sucralfate but this was not statistically significant.

**Endoscopic Scarring Stage**

Figure 2 shows the breakdown of the endoscopic scarring stages for the patients who had remained in remission during the trial and for those who had relapsed immediately before confirmation of the ulcer recurrence. Approximately 79% each of the relapse cases in each group developed from a red scar, whilst 83-5% of the non-relapse cases in the ranitidine groups and 71-4% of the non-relapse cases in the sucralfate group were in the white scar stage.

**Adverse Effects and Laboratory Abnormalities**

Adverse effects developed in three of 171 patients (1-8%) in the ranitidine group and in six of 175 patients (3.4%) in the sucralfate group. The three patients in the ranitidine group suffered from allergic symptoms including skin rash, aggravation of chronic eczema and skin itchiness, while the six cases in the sucralfate group complained of gastrointestinal symptoms comprising gastric distension (two cases), diarrhoea, heartburn, belching, abdominal pain, and nausea.

All the adverse effects developed during the first six weeks of the trial. Those symptoms resolved or were alleviated in all cases as the drug treatment was continued or stopped.

No clinically significant changes were detected in

( ) Number of cumulative patients.
routine biochemical tests (electrolytes, liver, and renal function tests) with the exception of a small increase in total serum bilirubin in one patient treated with ranitidine (0.7 mg/dl pre-trial, 1.3 mg/dl at six months, 1.5 mg/dl at 12 months) and a slight increase in LDH in one patient receiving sucralfate (357 IU/l pretrial, 384 IU/l at six months, 431 IU/l at 12 months).

**Discussion**

A number of clinical trials have been conducted with histamine H₂-receptor blockers, especially ranitidine and cimetidine to evaluate their efficacy in the prevention of peptic ulcer relapse. For both of these compounds the majority of trials have been conducted in duodenal ulcer patients. Gough et al.⁶ and Silvis et al.⁷ reported that ranitidine 150 mg/day, which has a stronger inhibitory effect on nocturnal acid secretion than cimetidine 400 mg (Santana et al.),⁸ showed significant superiority in terms of the cumulative relapse rate over 12 months. Reports on the prevention of gastric ulcer relapse are few. Barr et al.⁹ and Morgan et al.⁴ reported studies with cimetidine, but the number of enrolled patients were small and their data analysis techniques were not standardised. Boyd et al.¹⁰ and Cockel et al.¹¹ studied ranitidine’s effects on ulcer relapse by recruiting a large number of patients, and they reported cumulative relapse rates for one year of 22.6% and 17.1% respectively.

Sucralfate, the control drug for this trial, is widely prescribed in Japan for gastric ulcer treatment, and several papers¹²–¹⁴ have dealt with its use as maintenance therapy. In one of those reports, Marks et al.¹⁵ commented that the recommended therapeutic dosage for satisfactory prevention of gastric ulcer relapse is 3 g/day, given as 1 g between breakfast and lunch and 2 g before bedtime.

In our study, ranitidine 150 mg/day and sucralfate 1 g tds (method of administration differed from that reported by Marks et al.), were compared for their effects on gastric ulcer relapse. As a result, ranitidine showed a cumulative relapse rate for one year of 21.0%, and its effect on ulcer relapse was significantly superior to sucralfate (p<0.05) after nine and 12 months treatment. In the studies by Boyd et al.¹⁰ and Cockel et al.¹¹ the cumulative relapse rates for one year were also about 20%. For sucralfate, Marks et al.¹¹ reported a relapse rate of 16.0% for six months. Our relapse rate of 21.3% for six months was similar to their result.

In our study, endoscopic examination was conducted at three monthly intervals and at unscheduled
times whenever the symptoms warranted; this permitted accurate monitoring of asymptomatic recurrence. The total cumulative relapse rate and the cumulative symptomatic relapse rate for the open study of Boyd et al were 22.6% and 14.0%, respectively. Similar relapse rates of 21.0% and 12.7% were observed in our study, thus elucidating the ratio of symptomatic relapse to asymptomatic relapse of gastric ulcer in ranitidine maintenance therapy. In any case, in our comparative study enrolling a large number of patients, ranitidine, a histamine H₂-receptor blockers, showed satisfactory prevention of gastric ulcer relapse, in which a decrease in defensive factors is said to have a strong causal relation, in comparison with sucralfate, which has a mucosal protective action. This finding suggests that ranitidine is an effective drug for gastric ulcer maintenance therapy.

The gastric ulcer relapse rate peaked during the first three months of maintenance therapy, and this may be attributable to many factors, including previous ulcer treatment. Furthermore, there is a question as to whether the relapse observed in the first three months is a genuine relapse of merely incomplete prior healing.

Peptic ulcers are judged as healed by endoscopic confirmation of a scar. Generally, in Japan scars are classified as red scars and white scars. In a study on sucralfate in the prevention of gastric ulcer relapse, Miyake et al reported that relapse rates are higher from red scars, suggesting that endoscopic characterisation of the scar is useful for predicting ulcer relapse.

During our study relapse in both treatment groups was greater in patients with a red scar than those having a white scar. These observations suggest that it may be necessary to continue therapy at the therapeutic dosage until confirmation of a white scar, in contrast with concluding that a red scar is proof of healing.

There is considerable discussion regarding the safety of longterm administration, including maintenance therapy, of histamine H₂-receptor blockers, but because they have been clinically available for only 10 years, lifetime safety data are not available. On the other hand, sucralfate has been used for 20 years in Japan without serious side effects; it is a non-systemic drug and therefore it is a good choice in terms of safety of longterm administration.

All the areas of adverse effects in both drug groups in this study developed during the first three months, and no severe cases were observed throughout the year. For sucralfate, no untoward effects were noted which could have been ascribed to aluminium toxicity. Further studies over a longer period and including a larger number of patients are needed to establish the safety of longterm administration of histamine H₂-receptor blockers.

Based on the results of our study, administration of ranitidine, in a dose of 150 mg/day nocte for 12 months is more effective in preventing gastric ulcer relapse than sucralfate, in a dose of 1 g tds (before breakfast, lunch, and bed-time).

We are grateful to Dr John R Wood for his critical comments on this paper.
