SUMMARY The sequence of changes in the activity of six disaccharidases in the small intestine of gerbils during primary and secondary G lamblia infections was examined. The primary G lamblia infection induced a transient reduction in disaccharidase activity which was related to the highest trophozoite burden in the small intestine. During the primary exposure, a 30% to 85% decrease in the activity of enzymes was observed on days 10 and 20 after infection. Secondary exposure of gerbils to G lamblia caused a sharp decrease in disaccharidase activity as early as 24 h after challenge. The reduction in the enzyme activity was not influenced by the size of the challenge inoculum and occurred even when there were no live trophozoites in the small intestine. Disaccharidase deficiency could also be induced by challenge with the soluble extract of the trophozoites. Multiple challenge administrations of G lamblia trophozoites to gerbils induced a persistent disaccharidase deficiency. The results indicate that disaccharidase deficiency associated with the primary G lamblia infection probably represents a direct effect of the parasite on the brush border of the small intestine. On the other hand, the observed disaccharidase deficiency in the secondary G lamblia infection appears to be induced by the local immune responses of the host.

Various abnormalities of small bowel pathology have been identified consistently in human giardiasis and these include disaccharidase deficiencies, increased intraepithelial lymphocyte counts and, in patients with malabsorption crypt hyperplasia with short villi and increased lamina propria cellularity. Low serum calcium and folate concentrations were consistent features in elderly people having giardiasis and aroused suspicion of underlying malabsorption. A decrease in the disaccharidase activity has been observed in vitro. Mouse mucosal cells incubated with G lamblia trophozoites showed a reduction in the activities of lactase, sucrase, and maltase.

We have recently described an animal model for giardiasis using gerbils and G lamblia isolated from humans. In this study, we examined the progression of changes in the activity of six disaccharidases in the small intestine of gerbils during primary and challenge infections with G lamblia.

Methods

PARASITES Trophozoites of G lamblia, WB isolate, originally obtained from a symptomatic patient (American type culture collection no 30957) were used for experimental infections. Trophozoites were grown axenically in filter sterilised Diamond's TYI-S-33 medium using the procedures described previously.

ANIMALS Six to 10 week old male Mongolian gerbils (Meriones unguiculatus) were obtained from Tumblebrook Farms Ltd. (West Brookfield, Ma). The procedures for the maintenance of Giardia free animal colony have been described previously.
INOCULATION OF LAMBLIA TROPHOZOITES TO GERBILS
Two hundred thousand trophozoites of *G lamblia* were administered to gerbils either orally or by the duodenal injection technique of Belosevic and Dick.  

QUANTIFICATION OF TROPHOZOITES IN THE SMALL INTESTINE
The number of trophozoites per gerbil and their location in the small intestine were determined by the technique of Belosevic *et al.*  

PREPARATION OF THE SOLUBLE EXTRACT OF TROPHOZOITES
Trophozoites (48-96 h culture) were sedimented by centrifugation at 200 g for five minutes and washed three times in PBS at 200 g for 10 min. Trophozoites were disrupted by sonication in PBS. After sonication, the suspension was dialysed using Spectrapor membrane (Spectrum Medical Industries Inc, Los Angeles, California) against PBS for 24 h at 4°C. Protein concentration of each extract was determined using Bio-Rad protein determination kit (Bio-Rad Chemical Co, Richmond, Ca). This extraction method yielded approximately 0.5 mg of *G lamblia* protein from 2×10⁵ trophozoites.  

MEASUREMENT OF THE VILLUS: CRYPT RATIO
The method of Roberts-Thomson *et al.* for the determination of villus to crypt ratio in murine giardiasis was used except for the following modification. Small intestine was removed, opened longitudinally, fixed in 10% formalin, and processed in paraffin for light microscopy. All histologic specimens (haematoxylin-eosin 8 μm) were examined at 400× and measurements made with an ocular micrometer. The height of the villi and crypts was determined on 10 representative specimens of infected and uninfected gerbils.  

MEASUREMENT OF INTESTINAL DISACCHARIDASES
*Preparation of intestinal homogenate*
Gerbils were killed by cervical dislocation and the small intestine was removed and divided into four equal sections. The segments were placed in ice cold distilled water and flushed with 50 ml distilled water using a syringe fitted with a cannula. The intestinal segments were then placed on top of an ice cold ground glass slab and were slit longitudinally. The mucosa was scraped from the intestine with a glass microscope slide, weighed (wet weight), and placed in 4 volumes of ice cold distilled water. The mucosal scrapings were homogenised using glass/Teflon homogeniser (10 strokes, using a Con Torque power unit at maximum speed; Eberbach Corp, Ann Arbor, MI). The homogenates were then centrifuged at 400 g for five minutes in order to remove larger cell debris. Cell debris obtained during the preparation of homogenates from uninfected, infected and challenged gerbils was assayed and found to have marginal disaccharidase activity which was not significantly different between the experimental groups. After centrifugation, the homogenates were stored in liquid nitrogen in 0.2 ml aliquots until used in the assays.  

Reagents
All substrates were obtained commercially. Glucose (D-16) and sucrose (S-5B) were purchased from Fisher Scientific Co. (Montreal, Que). Maltose (M-5885), cellobiose (C-7252), lactose (L-3750), trehalose (T-5251) and isomaltose (I7253) were obtained from Sigma Chemical Co (St Louis, Mo). Chemicals for the glucose oxidase reagent were also obtained commercially. Sigma 7-9 Tris buffer (T-1378). Triton X-100 (X-100), o-dianisidine (D-9143), peroxidase (P-8000) and glucose oxidase (G-1262) were obtained from Sigma.  

*Assay for intestinal disaccharidases*
Disaccharidase activity of mucosal scrapings was assessed using modified glucose oxidase peroxidase enzyme system. The assay was done in 96-well Linbro microtitre plates (Flow Laboratories, Toronto, Ont). The assay consisted of adding to each well 0.01 ml appropriately diluted mucosal sample and 0.01 ml substrate buffer solution of a disaccharidase to be measured in triplicate. The plates were incubated at 37°C in humidified atmosphere for 60 min. After incubation, 0.3 ml of tris-glucose oxidase (TGO) reagent was added to each well and the plates were incubated for an additional 60 min. The plates were read at 414 nm using a microplate reader (Titertec Multiscan, Flow). For each assay, eight reagent blanks (0.02 ml distilled water and 0.3 ml TGO reagent) and two glucose standard series (2, 6 and 10 μg glucose) were also done. Throughout this paper, disaccharidase activity will be expressed as units/g of the mucosal sample.  

STATISTICAL ANALYSIS
Data were analysed by Student's *t* test and one-way analysis of variance (ANOVA), using BIOM statistical programs for the IBM personal computer. The probability level of *p*<0.05 was considered significant.  

Results
*Course of Infection*
Trophozoite colonisation of the small intestine of
were compared. The number of trophozoites that colonised the small intestine during the infection was similar in orally and duodenally inoculated gerbils. Highest trophozoite loads in the gut were observed on days 10 and 15 after infection in both groups. On day 15 after infection, the mean number of trophozoites in orally inoculated gerbils was 4.8 (1.9) × 10^6/gerbil and that of duodenally inoculated gerbils was 6.6 (1.5) × 10^6/gerbil. The number of trophozoites in the small intestine sharply decreased after day 20 of infection in both orally and duodenally inoculated animals.

Mean body weight of gerbils in experimental and control groups at the beginning of the experiments was 42 (3) g and 41 (2) g, respectively. At the end of the experiments the mean body weight of gerbils infected with G lamblia was 63 (5) g and that of control uninfected animals was 67 (4) g. There were no differences in mean body weight between infected and uninfected gerbils (p >0.05, one-way analysis of variance).

Measurement of villus/crypt ratio during primary infection
The villus to crypt ratio in the duodenum of gerbils infected with 2 × 10^6 Giardia trophozoites was determined every five days for a period of 35 days (Fig. 1). A significant decrease in the villus to crypt ratio occurred at day 10 to 20 after infection (p <0.05, one-way analysis of variance). At 25 to 35 days, however, the villus to crypt ratio returned to normal, a period which corresponds to the elimination of the trophozoites from the duodenum.

Measurement of intestinal disaccharidases
Disaccharidase activity during the primary infection
A 30% to 85% decrease in the activity of all disaccharidases, except cellobiase, was observed during the acute phase of the infection (Fig. 2). The decrease in the activity of the enzymes was related to the period of highest trophozoite burden in the small intestine. Significantly lower activities of maltase, isomaltase and sucrase were detected on days 10 and 20 of the primary infection. The activity of these disaccharidases returned to normal levels during the elimination phase of the infection (days 30 and 40). The decrease in trehalase activity occurred later (day 20 after infection), and persisted longer (up to day 30 after infection), when compared with that of maltase, isomaltase and sucrase.

The decrease in disaccharidase activity was observed in all sections of the small intestine (data not shown). Isomaltase activity in the small intestine of gerbils was consistently higher than either maltase or sucrase activity, which is the opposite to that observed in man. The difference in the enzyme activity profiles may be due to the animal species used. Thus, G lamblia infection induced transient reduction in maltase, isomaltase, sucrase and trehalase evident during the highest parasite density in the small intestine. With a low number of trophozoites present in the intestine (before day 10) or with a decrease in the number of organisms on days 30 and 40, the activities of these disaccharidases returned to normal levels. On the other hand, lactase activity was significantly reduced during the acute and elimination phases of the infection and was not related to the trophozoite burden in the small intestine (Fig. 2).

Disaccharidase activity at various times after a challenge infection
Challenge inoculation of gerbils with G lamblia trophozoites resulted in a sharp decrease in disaccharidase activity in the small intestine (Fig. 3). This reduction in enzyme activity occurred in the absence of trophozoites as the organisms were not observed in
the gut of all challenged gerbils. Sucrase and trehalase activity profiles after a challenge were similar (Fig. 3). For example, a significant reduction in sucrase and trehalase activity was observed as early as day 1 after challenge and on days 2, 4 and 8 after challenge infection. The activities of sucrase and trehalase returned to normal levels by day 16 and 30, however, after the challenge infection, indicating that this depression in disaccharidase activity was transient. Similar results were obtained for lactase activity except that significantly lower activity was also observed on day 16 after challenge (Fig. 3). The decrease in disaccharidase activity of similar magnitude was also observed in posterior small intestine.

A reduction in disaccharidase activity upon challenge was also observed long after the primary infection. When gerbils were challenged on day 150 after the primary infection, a significantly lower sucrase, trehalase and lactase activity was observed on day 4 after the challenge when compared with age-matched animals which did not receive a challenge infection.

Disaccharidase activity in the small intestine of gerbils given different challenge doses

The size of the challenge inoculum did not significantly affect the degree of disaccharidase deficiency (data not shown). Enzyme activity after challenge with different numbers of trophozoites was similar between gerbils given low doses ($5 \times 10^4$, $1 \times 10^4$) and those given high doses ($8 \times 10^4$, $1.6 \times 10^4$). It should be noted, however, that except for cellobiase and lactase, the activity of the remainder of disaccharidases in challenged animals was significantly lower when compared with that in gerbils on day 40 after the primary infection.
Disaccharides in giardiasis

*For each group six gerbils were inoculated orally with 2×10⁷ trophozoites each. On day 40 after the primary infection and on 10 day intervals thereafter, gerbils were challenged with 2×10⁷ trophozoites each. For all groups, the disaccharidase activity was measured on day 4 after the last challenge infection. Except for cellobiase, all groups were significantly different (p <0.05, Student’s t test) when compared with the no challenge group.

Disaccharidase activity in the small intestine of gerbils after repeated challenge infections

Repeated challenge inoculations of gerbils with G lamblia trophozoites resulted in persistent disaccharidase deficiency. As shown in Table 1, the activities of maltase, isomaltase, sucrase, trehalase and lactase remained low after 2, 3, and 4 challenge inoculations given on 10 day intervals. The data indicate that frequent re-exposure of gerbils to G lamblia results in continuous low enzyme activity long after the primary infection in the absence of trophozoites in the small intestine.

Disaccharidase activity after challenge with the soluble extract of trophozoites

As shown in Table 2, challenge of gerbils previously exposed to G lamblia with the soluble extract of trophozoites resulted in significant reduction in disaccharidase activity. This decrease in enzyme activity was comparable to that induced by challenge with live trophozoites. The amount of the soluble extract administered did not affect the degree of disaccharidase deficiency, because the reduction in enzyme activity was similar between animals challenged with 0.5 mg of the soluble extract and those challenged with 2 mg. The results show that the reduction in maltase, sucrase, trehalase and lactase activity upon challenge occurred in the absence of live G lamblia trophozoites.

Discussion

There is enormous variability in both the clinical features and pathological changes associated with giardiasis in man. The degree of pathological damage to the small intestine has been correlated to the symptoms. At present, we have little knowledge of the relative contributions of parasite and host related factors to the pathogenesis of giardiasis. For example, changes caused directly by the parasite, such as the damage to the microvillous border of the small intestine, may be related to the parasite burden in the gut. On the other hand, changes resulting from the host response can be identified by manipulating host factors such as immunity and nutrition. The gerbil G lamblia model for giardiasis, provides the means whereby these components can be analysed separately.

In this study we have examined the progression of changes in the activity of six disaccharidases in the small intestine of gerbils during primary and secondary infections with G lamblia. Because the majority of trophozoites were located in the upper small intestine of gerbils during the infection, we measured enzyme activities in the duodenum, proximal and distal jejunum and ileum. The results show that G lamblia induced a transient decrease in disaccharidase activity during the acute phase of the primary infection. This decrease in the enzyme activity was related temporally to the highest trophozoite burden in the small intestine, and was observed in all regions.

*Five gerbils per group were infected with 2×10⁷ trophozoites each on day 0. On day 40 after the primary infection, gerbils were challenged with 2×10⁷ trophozoites or were given orally 0.5 mg of the soluble extract of trophozoites at a rate of 0.5 mg/gerbil/day. Four days after the last administration of the extract, disaccharidase activity was measured. All groups were significantly different (p <0.05, Student’s t test) when compared with the no challenge group.
of the gut during the acute phase of the primary infection. There were also differences in the activity profiles of the enzymes. For example, the reduction in maltase, isomaltase, and sucrase activity was observed on days 10 and 20 after infection, whereas that of trehalase occurred later (days 20 and 30 of infection). A notable exception was lactase activity which remained low during both the acute and elimination phases of the infection and was not related to the trophozoite burden in the small intestine. Our results support, in part, those of Gillon et al., who showed that maltase, sucrase and lactase levels in the duodenum of mice infected with *G. muris* were reduced significantly during the second week after infection. These authors also reported that lactase activity in the duodenum returned to normal levels by week 10 after infection. This was not observed in our study, as lactase levels remained low during both the acute and elimination phases of the infection. The discrepancy in the findings may be due to different species of the parasite and different host used.

This is the first study that has examined disaccharidase activity after a secondary exposure to Giardia. Challenge inoculation of gerbils with *G. lamblia* trophozoites resulted in a sharp and immediate decrease in the activity of the enzymes in both anterior and posterior small intestine. Lower activities of sucrase and trehalase were observed until day 8 and lactase until day 16 after challenge. This reduction in the enzyme activity was not dependent on the size of the challenge inoculum and it occurred in the absence of trophozoites, as the organisms were not observed in the small intestine of any of the challenged gerbils. Moreover, challenge of gerbils previously exposed to *G. lamblia* with the soluble extract of trophozoites resulted in a significant reduction in disaccharidase activity, comparable with that induced by challenge with live trophozoites. These results indicate that a secondary exposure of gerbils to *G. lamblia* resulted in disaccharidase deficiency similar in magnitude to that observed during the primary *G. lamblia* infection.

The decrease in disaccharidase activity upon challenge in the apparent absence of trophozoites in the small intestine as well as after administration of the soluble extract of trophozoites suggest that disaccharidase deficiency may be controlled by both parasite and host related factors. During the primary *G. lamblia* infection, the disaccharidase deficiency associated with giardiasis is likely to represent a direct effect of the parasite on the brush border. In this case, maximal reduction in enzyme activity should correlate with the highest trophozoite load in the small intestine. Our results support this hypothesis because greatest reduction in disaccharidase levels occurred during the acute phase of the infection.

On the other hand, the reduction in enzyme activity upon challenge with live trophozoites or the soluble extract of the trophozoites suggests that disaccharidase deficiency may be caused by the local immune response of the host. It is known that gerbils previously exposed to *G. lamblia* are resistant to reinfection for at least eight months after the primary infection. We have recently shown that the resistance of gerbils to reinfection could occur in both the absence or presence of occult *G. lamblia* infection. These findings suggest that the immune response of the host is involved in the resistance to Giardia and that this resistance is of relatively long duration. It is interesting to note that secondary exposure of gerbils to *G. lamblia* as long as 150 days after the primary infection results in disaccharidase deficiency of similar magnitude to that observed during the primary infection. Our findings indicate that frequent re-exposure of the host to Giardia may affect the nutritional status of the host by reducing the carbohydrate uptake. It remains to be determined whether re-exposure to other gastrointestinal parasites would result in disaccharidase deficiency in host’s intestinal mucosa.
