The diarrhoea of famine and severe malnutrition – is glucagon the major culprit?

Intractable diarrhoea is usually the terminal condition of victims of famine and severe malnutrition. Despite many studies on the effects of starvation and malnutrition on the absorptive functions of the small intestine in animals, and a few in man, no satisfactory explanation exists for this diarrhoea. While it has often been attributed to bacterial infection, extensive bacteriological studies failed to confirm this and it is estimated that only approximately 15% of cases have a diarrhoea of infectious origin. In the most detailed analysis of the effects of extreme malnutrition on Danish subjects (who had been incarcerated in a concentration camp), Helweg-Larsen, Hoffmeyer, Kieler et al identified three types of diarrhoea. The most prevalent was an endemic, progressive, afebrile 'diarrhoea diarrhoea' while 'infectious diarrhoea' was infrequent. Sudden realiamentation caused an 'alimentary diarrhoea'. All were potentially lethal in the severely weakened state of the subjects. According to Roediger, the terminal diarrhoea of kwashiorkor and marasmus (corresponding to hunger diarrhoea) is the result of lack of luminal nutrition of enterocytes, and especially of colonocytes, which severely reduces their absorptive function. In his explanation, the diarrhoea is mainly caused by the loss of the reabsorptive (salvage?) capacity of the colon.

Ethical problems prevent controlled studies on the secretory behaviour of the intestine in starved and severely malnourished individuals but their lack in an experimental animal model is surprising. In order to investigate the effects of starvation and undernutrition on the secretory function of the small and large intestine, the rat has been used as an animal model. Starvation for 24 hours did not significantly alter small intestinal secretory function but between 24 and 72 hours of starvation the duodenum, jejunum, and ileum all showed hypersecretory activity compared with fed intestine when activated to secrete by neurotransmitters and secretagogues. Moreover, in the case of the ileum, even the fed basal absorptive tone was converted to a secretory one after 24 hours of food withdrawal and its magnitude increased on continued food deprivation. Further studies showed that the proximal colon, and even the rectum, from rats starved for three days responded to cholineric agonists by electrogenic Cl⁻ hypersecretion. Analysis of the types of secretory responses elicited by various neurotransmitters, bacterial toxins, and secretagogues showed clearly that in the case of the small intestine, all of these agents caused a hypersecretion in the starved rat. In the proximal colon, however, only those agents that activate secretion by increasing intracellular Ca²⁺ (cholinergic agents, 5-hydroxytryptamine (5HT), A 23187) elicited the hypersecretory response, those acting through increases in intracellular cyclic adenosine monophosphate (AMP) (theophylline, dibutyryl cyclic adenosine monophosphate, forskolin, and prostaglandin) or in mid colon through cyclic guanosine monophosphate (Escherichia coli STa) did not cause electrogenic Cl⁻ hypersecretion. In fact, they often elicited less secretion compared with the fed state. This lack of effect of cyclic AMP mediated secretagogues to induce hypersecretion has not been confirmed in the starved mouse colon. The hypersecretion is not caused by any significant change in the enteric neural innervation of the small intestine as it could be obtained even in the presence of the neural toxin tetrodotoxin, nor is there any significant change in the enteroctye's receptor sites for the neural transmitters as the hypersecretion could be obtained with agents that bypassed these sites. However, cyclic AMP concentrations were higher in enterocytes from starved intestine, both in the basal state and when stimulated by secretagogues. The reversal of the basal absorptive tone in the fed ileum to a secretory one correlated well with the increase in cyclic AMP found in this area on starvation. Confirmation of the hypersecretory action of starvation on small intestinal secretory function in vitro has been reported in the jejunum of starved piglets.

The obvious question that arises from the rat studies is, what causes the hypersecretory behaviour of the enterocytes and colonocytes? Before we can answer this, it is necessary to describe briefly the current model for the secretory behaviour of enterocytes (and colonocytes). Chloride is transported into the cells against its electrochemical gradient by the Na⁺-K⁺-2Cl⁻ cotransporter in the basolateral membrane. The intracellular Na⁺ ion concentration is kept low by the action of the Na⁺-K⁺-adenosine triphosphatase pump, also in the basolateral membrane, pumping out 3 Na⁺ ion in exchange for 2 K⁺ ions. The membrane is also equipped with K⁺ channels that when opened allow the K⁺ to leave the cell under the influence of the K⁺ gradient. At the luminal brush border of the cell, Cl⁻ channels which are normally closed can be opened by intracellular second messengers (possible cyclic AMP or Ca++) allowing the intracellular Cl⁻ ions to be driven out of the cell by their concentration difference and the transmembrane membrane potential difference (pd, cell interior negative to the lumen) as electrogenic Cl⁻ secretion. This outward movement of CI⁻ depolarises the luminal membrane potential, which reduces the driving force and attenuates CI⁻ secretion. Secretagogues, however, activate the basolateral K⁺ channels (probably by the raised intracellular Ca++,), and the passive outflow of intracellular K⁺ hyperpolarises the membrane. Electrical coupling via the intercellular pathway maintains the luminal membrane pd which preserves the electrical potential drive for the Cl⁻ movement. The activation of the enterocyte's luminal Cl⁻ and basolateral K⁺ channels is normal via the cholinergic and vipergic neurotransmitters acetylcholine and vasoactive intestinal polypeptide (mediated through intracellular second messengers) but other agencies such as prostaglandins, SHT, bacterial toxins, and various hormones can also directly or indirectly activate secretion.

Starvation in the rat reduces the mitotic activity in the duodenal/jejunal crypts, they decrease in size and the supply of new enterocytes onto the villus is slowed. As old enterocytes are still sloughed off at the villi tip, the cells of the villus height, and cell population decrease. At first it is tempting to explain the decreased secretion of the starved small intestine as being the result of this decreased cell turnover and villus size on the basis of the simplistic model that villi absorb and crypts secrete. If the decreased enterocyte population on the villi had a reduced absorption while the crypts secreted even normally, then the imbalance could cause an apparent hypersecretion. We have previously
discussed this as being unlikely for a number of reasons. Firstly, in the starved state the enterocytes are on the villus longer and this ageing seems to increase their absorptive functions; secondly, the crypt population also decreases yet secretion increases; thirdly, the enterocytes on the villus are now known to be able to secrete Cl- electrogenically; and finally, there is controversy as to whether human villi do decrease in size in conditions known to reduce luminal electrolyte transport. Thus explanations other than the changed balance between crypt and villous enterocytes must be sought.

The luminal membranes of the starved enterocytes in both the jejunum and the ileum becomes hyperpolarised after only 24 hours of fasting and is maintained for at least 72 hours of starvation. This membrane hyperpolarisation creates an increased driving force on the intracellular Cl- ions when the Cl- channels of the luminal membrane are opened by neurotransmitters or secretagogues. Thus the hyperpolarisation of the starved enterocyte’s luminal membrane can account for the hypersecretory activity shown by the small intestine in the food deprived state. However, as described previously, the loss of Cl- via the channels will decrease the transluminal membrane pd and reduce secretion so the K+ channels of the enterocyte have also to be included in the mechanism to maintain the luminal membrane pd by their activation and subsequent electrical coupling with this membrane. The increased transluminal membrane pd in the starved enterocytes also affects the charged Na+-glucose or amino acid linked cotransporter of the luminal membrane creating an enhanced electrogenic nutrient transfer.2,17

One intriguing point that needs comment is that measurements of the enterocyte’s transluminal membrane pd after 24 hours of fasting show an obvious increase but assessments of their fluid and electrogenic secretion only become significant after 24–48 hours of starvation.14,15 A possible explanation for this apparent inconsistency may simply be the different sensitivities of the two techniques. As microelectrode pd measurements are on individual enterocytes, it is possible to assess changes in a small population at or near the top of the villus. The fluid and electrogenic secretory responses are, however, macro measurements needing a large number of enterocytes to be affected before significant differences can be distinguished. It is thus possible that the first changes after 24 hours of starvation are expressed in the mature cells on the upper part of the villus. The enterocytes lower down the villus follow, but some 24–48 hours later.

The hyperpolarisation of the luminal membrane is caused by a reduction in its passive Na+ permeability as the membrane pd in starved enterocytes did not show the linear-log relation with changes in Na+ concentration observed in fed enterocytes.16 The changes seemed specific for Na+, as the K+ permeability of the membrane in fed and starved intestine was identical. Murer, Hopfer, and Kinner,17 working with brush border membrane vesicles from fed rat enterocytes, showed that cyclic AMP reduces the passive permeability of the luminal membrane to Na+. Presumably, the increased concentrations of cyclic AMP in the starved enterocytes will also influence membrane Na+ permeability creating the hyperpolarisation of the luminal membrane.

We can dissect the mechanism of the hypersecretion even further. In starvation, the plasma glucagon in both rat18 and man19 is increased; in man it plateaus at a new, higher than fed, value.20 The raised glucagon stimulates the intestinal uptake of amino acids and glucose as antilagucagon, when injected in starved rats, prevents the enhancement.20 Even in fed rats, repeated glucagon injections for three days increase the ileal absorption of glucose.21 The hyperglucagonaemia increases the transluminal membrane pd of jejunal enterocytes22 in fed rats (from a mean value of −48 mV to −54 mV) and stimulates the uptake of Na+-dependent glucose and amino acids. It is highly likely that the chronic increase in plasma glucagon brought about by starvation induces changes in the enterocytes (perhaps by raising cyclic AMP levels?) creating the hyperpolarisation of the luminal membrane which can then give rise to the various enhanced transport properties of the starved intestine. Interestingly, even when added directly to small intestine in vitro, glucagon has been shown to cause Cl- secretion across mouse jejunum,23 and when acutely injected causes jejunal secretion in human subjects in vivo.24

At present all the experimental evidence linking glucagon with the hypersecretion of starvation is only attributable to the small intestine. It is not known whether glucagon is also involved in the hypersecretion induced in the colonocytes. Even if further experimental studies show that glucagon is implicated in colonic hypersecretion an explanation has to be sought for the finding that isolated colonocytes respond to Ca2+ secretagogues by hypersecretion but not to those mediated by cyclic AMP.

One final problem remains, namely, how is intestinal secretion activated in the starved animal or human? In both humans and rats in the fasted state, a regular propagated wave of electrical and smooth muscle activity called the migrating myoelectric complex (MMC) passes down the small intestine. Food disrupts the regularity of the activity. The MMC activates secretion in the stomach and pancreas when it passes down the tract and increases transiently the transmural electrical pd across the small intestine.25,26 This increase was interpreted as being the result of neural activation of electrogenic Cl− secretion.27,28 Recordings obtained across the small intestine of cystic fibrosis patients have confirmed this interpretation, because the subjects do not show such electrogenic secretory activity as their intestines cannot secrete Cl− electrogenically.29 Thus the MMC continually passes down the starved intestine (both in rats and in humans) stimulating the enteric plexus to activate the cellular hypersecretion. Other possible luminal activators of secretion are bacterial toxins30 and even viral intestinal agents.31 The net result of all these agencies is to make the starved intestine secrete excessive amounts of fluid and thus create diarrhoea by overloading the depressed absorptive function of the colon.32

Preliminary studies in rats have shown that the simple drinking of glucose during the three day starvation, while greatly ameliorating the hypersecretion in the duodenum, jejunum, and ileum, leaves the colon’s hypersecretory activity unaffected.33 The rat model also offers the possibility of investigating dietary regimens that will not only ameliorate both small and large intestinal hypersecretory activity of starvation but will also act as stimulants for their absorptive functions.34
