Peripheral blood monocyte cytokine production and acute phase response in inflammatory bowel disease

M Z Mazlam, H J F Hodgson

Abstract
Cytokines released from activated mononuclear leukocytes are involved in triggering the acute phase response and many of the inflammatory manifestations of ulcerative colitis and Crohn’s disease. The ability of circulating monocytes from patients with ulcerative colitis and Crohn’s disease to generate the cytokines interleukin 1β (IL 1β) and tumour necrosis factor alpha (TNF α), both spontaneously and in response to stimulation by lipopolysaccharide, was compared. IL 1β generation in response to lipopolysaccharide was significantly higher in Crohn’s disease than in ulcerative colitis and normal controls, with a dramatic increase in patients with active disease. There was a significant reduction in lipopolysaccharide stimulated TNF α generation in ulcerative colitis patients compared with Crohn’s disease and normal control subjects. IL 1β and TNF α release correlated significantly with serum C reactive protein and serum α1 acid glycoprotein in Crohn’s disease. The ability of conditioned medium from monocytes in Crohn’s disease to enhance release of α1 acid glycoprotein from the liver cell line HepG2 in culture was assessed. There was a significant positive correlation between TNF α and IL 1β presence in the supernatant and α1 acid glycoprotein production. The differences in the cytokine profile in patients with Crohn’s disease compared with ulcerative colitis suggest an intrinsic difference in the ability to produce cytokines in patients with these two forms of inflammatory bowel disease, and may explain features such as the enhanced ability to generate a brisk C reactive protein response in Crohn’s disease.

Although most cases of inflammatory bowel disease can be classified as either ulcerative colitis or Crohn’s disease on the basis of clinical and histopathological appearances, many of the inflammatory mechanisms involved at the tissue level in the two conditions are identical. Serum concentrations of correlates of inflammation – such as C reactive protein, α1 acid glycoprotein (or orosomucoid), and neutrophil elastase – have been extensively studied, largely because these objective parameters may help assess the inflammatory process either in individual patients or in clinical trials. This is particularly useful in Crohn’s disease where the correlation between symptoms and the presence of inflammation may be poor. In comparing ulcerative colitis and Crohn’s disease, differences in the circulating levels of some laboratory markers have emerged, even when attempts are made to compare patients with apparently similar degrees of clinical severity. Thus C reactive protein levels,2 serum amyloid A associated protein,3 and neutrophil elastase1 are generally significantly higher during active Crohn’s disease than during active ulcerative colitis, although α1 acid glycoprotein and α1-antichymotrypsin show a similar increase.

There may be relatively trivial explanations for the differences in serum levels of parameters of inflammation between the two conditions. For example, the lower elastase concentrations found in ulcerative colitis may merely reflect the more superficial distribution of inflammation, compared with Crohn’s disease, and consequent loss of elastase released from polymorphonuclear leukocytes into the gut lumen rather than into the circulation. An alternative explanation is that these differences reflect differences in the nature of the inflammatory processes occurring in these two conditions. Differing inflammatory processes might reflect different aetiologies of ulcerative colitis and Crohn’s disease; alternatively, even if the initiating factor for inflammatory bowel disease is the same, a differing genetic background might predispose to expression of a particular form of inflammatory response, resulting in development of one or other form of inflammatory bowel disease.

Recent studies have begun to elucidate the process leading to the generation of serum proteins such as C reactive protein and α1 acid glycoprotein, showing the hepatic origin of these proteins, and that hepatic synthesis of these acute phase reactants is rapidly up-regulated in response to various cytokines released from inflammatory cells. In particular, the role of the mediators interleukin 1 (IL 1), tumour necrosis factor α (TNF α), and interleukin 6 (IL 6) (monocytic hepatocyte stimulating factor) have been emphasised.14 In inflamed tissue, the generation of this family of polypeptides from macrophages is substantially enhanced. In the context of inflammatory bowel disease, the noted differences in circulating concentrations of acute phase proteins between Crohn’s disease and ulcerative colitis may reflect qualitative differences in the cytokines produced in inflamed tissue, or again, reflect trivially, differences only in the number of macrophages involved in the inflammatory process.

We therefore investigated the ability of cells of the monocyte-macrophage lineage from patients with ulcerative colitis and Crohn’s disease, to release the cytokines IL 1β and TNF α. We quantified release of these cytokines from peripheral blood monocytes during both active and quiescent disease, and compared the results with those from normal control subjects.

Methods

PATIENTS AND CONTROLS

Three groups were investigated: group I, Crohn’s disease, 22 patients comprising 11 men and 11 women (mean (SD) age, 41.9 (15.1) years; range 23-69 years); group II, ulcerative colitis, 21 patients comprising 16 men and five women (mean age, 52.2 (19.2) years; range 22-79 years); group III, controls, 11 healthy individuals comprising six men and five women (mean age, 40.8 (13.2) years; range 27-65 years). The diagnosis of ulcerative colitis or Crohn’s disease was based on clinical, radiological, endoscopic, and biopsy findings.

DISEASE ACTIVITY

In Crohn’s disease activity was assessed by a simple index of Crohn’s disease activity, 0-15 (Harvey and Bradshaw, 1980). An index of ≤1 was defined as corresponding to quiescent disease and one of ≥2 to active disease. In this group, 11 patients had quiescent disease and 11 suffered from active disease. Ten patients with inactive disease had a simple index of 0 and one had a simple index of 1. Those with active disease had a mean (SEM) simple index of 4.6 (0.7); range 2-10. In terms of the extent of the disease, 12 patients had ileitis, seven ileocolitis, and three colitis.

Patients with ulcerative colitis were assessed as being in remission or having mild, moderate, or severe disease (Truelove and Witts, 1955). There were 10 patients in the ulcerative colitis group who had active disease and 11 patients who had inactive disease, with one patient whose disease subsequently became active. Of the patients in the active group, six were mildly active and five had moderately active disease. In terms of disease distribution, four patients had pancolitis, 12 had left colon involvement (of which two had proctosigmoiditis), eight had involvement of the rectum, sigmoid, and descending colon, and two had involvement of the rectum, sigmoid, descending, and transverse colon, and five had disease limited to the rectum.

TREATMENT

In the Crohn’s disease group, nine patients were not on treatment. Two patients were receiving sulphasalazine and five were being treated with 5-aminosalicylic acid; one of these was also receiving prednisolone. One patient was receiving fluticasone propionate, four patients were receiving prednisolone alone, and one patient was treated with prednisolone and azathioprine. In the ulcerative group, three patients were not on treatment. Nine patients were receiving sulphasalazine and six were on treatment with 5-aminosalicylic acid; one of these was also receiving prednisolone. One patient received steroid enemas, one received prednisolone alone, and one received treatment with prednisolone and azathioprine.

SEROLOGICAL INVESTIGATIONS

Serum was separated from clotted venous blood and stored at −20°C. Serum C reactive protein and serum α1-acid glycoprotein measurements were done by enzyme linked immunosorbent assay (ELISA). Briefly, polyclonal 96-well microtitre plates (Dynatech, USA) were coated with goat anti-human C reactive protein (Miles Laboratories Inc) or goat anti-human α1-acid glycoprotein (Sigma) in 0.05 mol/l sodium carbonate, pH 9.6, overnight at 4°C. These coated plates were then washed and incubated with serum samples and various dilutions of C reactive protein (Behringwerke) or α1-acid glycoprotein (Sigma) for standard curves. Peroxidase conjugated rabbit anti-human C reactive protein or rabbit anti-human α1-acid glycoprotein followed by peroxidase conjugated swine antirabbit immunoglobulins were then added to the plates. After further incubation, the plates were washed and developed with orthophenylenediafine. The intensity of the colour was measured at 492 nm.

MONOCYTE SEPARATION AND INCUBATION

Twenty ml of EDTA treated blood were diluted 1:3 with Hanks’ balanced salt solution (HBSS), and mononuclear cells were separated on a Ficoll density gradient (Nycomed). Peripheral blood mononuclear cells were collected from the interphase and washed twice, once in HBSS and the second wash in RPMI 1640 media (Gibco, UK). Cells were then resuspended in RPMI 1640 media supplemented with 10% (v/v) heat inactivated fetal calf serum, 4 mmol/l L-glutamine, 100 IU penicillin per ml, 100 μg streptomycin per ml, and 25 mmol/l HEPES buffer (complete medium). The concentration of monocytes was adjusted to 2 × 10⁶/ml by staining for peroxidase positive cells. The mononuclear preparation was then plated on 60 mm tissue culture plates (Nunclon) and these plates were incubated for two hours at 37°C in a 5% CO₂:95% air tissue culture incubator to allow the monocytes to adhere firmly to the plates. The non-adherent lymphocytes and platelets were removed by washings with warm serum free RPMI 1640 media to ensure pure monocytes were obtained. The viability of the adherent monocytes was greater than 95% and peroxidase staining of the non-adherent cells confirmed that the washing procedure did not significantly displace adherent monocytes.

CYTOKINE GENERATION AND MEASUREMENT

Monocyte cultures were divided into two groups with or without stimulation by 10 μg/ml lipopolysaccharide (Sigma). After incubation for 48 hours at 37°C, conditioned media were collected, centrifuged, and stored at −20°C. Preliminary experiments had shown that 48 hours incubation in conditioned medium had the greatest effect in stimulating α1-acid glycoprotein synthesis and depressing albumin synthesis in cultures of HepG2 cells. An ELISA technique was employed to measure IL-1β in monocyte conditioned media. In this assay system, various dilutions of recombinant human IL-1β were used (British Bio-technology) for a standard curve. The antibodies employed were rabbit
Peripheral blood monocyte cytokine production and acute phase response in inflammatory bowel disease

**Anti-recombinant human IL-1β (Universal Biologicals, UK); goat anti-recombinant human IL-1β (British Bio-technology, UK), which has no cross reactivity with IL-1α, IL-2, IL-6, tumour necrosis factor alpha (TNF-α) or TNF-β; and peroxidase conjugated donkey anti-goat IgG (Jackson Immunoresearch Lab, USA). TNF-α in monocyte conditioned media was also measured by ELISA.15 The lower detection limit of the IL-1β assay was 20 pg/ml, and the TNF-α assay 10 pg/ml. There was no cross reaction between these two assays; and in addition IL-6 and IL-1α did not interfere with the assay.**

**Stimulation of acute phase response in HepG2 cells with monocyte conditioned medium**

For stimulation of acute phase response proteins, HepG2 cells were trypsinised and a suspension in 25 ml complete medium at 100,000 cells/ml was established. Aliquots (1 ml) were placed into 24 well tissue culture plates and HepG2 cells were allowed to reach confluence. Equal volumes of monocyte conditioned medium and fresh complete medium were added and incubated in a 5% CO₂:95% air tissue culture incubator. After 60 hours, supernatant media were collected and analysed for levels of secreted α1 acid glycoprotein.

**Statistics**

Non-parametric procedures were employed for statistical significance testing. Comparisons between groups were assessed by Kruskal-Wallis, Wilcoxon signed rank test, and the Mann-Whitney U-test. Correlation coefficients were calculated using Kendall rank correlation test.

**Results**

**Peripheral blood monocytes**

The number of peripheral blood monocytes was mean (SEM) 3·2 (0·6)×10⁹/ml for ulcerative colitis, 3·6 (0·6)×10⁹/ml for Crohn’s disease, and 3·3 (0·3)×10⁹/ml for normal controls, with no significant differences between the three groups. However, among the patients with inflammatory bowel disease, those who had active inflammation (4·0 (0·7)×10⁹/ml; p<0·05 Wilcoxon) had greater monocyte counts than those without active disease (2·8 (0·2)×10⁹/ml). In patients with active ulcerative colitis (4·1 (1·1)×10⁹/ml; p<0·01 Wilcoxon) the number of peripheral blood monocytes is significantly higher than in patients with inactive disease (2·4 (0·3)×10⁹/ml). In active Crohn’s disease (3·9 (1·1)×10⁹/ml), the number of peripheral blood monocytes showed a similar trend compared with patients with inactive disease (3·2 (0·3)×10⁹/ml) but the difference did not reach statistical significance.

**In vitro production of TNF-α**

Spontaneous release of TNF-α in Crohn’s disease (52·2 (20·1) pg/ml) was not significantly different to the values in ulcerative colitis patients (25·2 (7·7) pg/ml) and normal controls (87·2 (32·1) pg/ml).

Lipopolysaccharide stimulated TNF-α generation in Crohn’s disease (177·5 (66·1) pg/ml) was similar to that in normal controls (196·3 (50·5) pg/ml), although patients with active disease (286·8 (125·4) pg/ml) showed higher but not statistically significant levels of lipopolysaccharide stimulated TNF-α than normal controls.

Lipopolysaccharide stimulated TNF-α generation in ulcerative colitis (59·4 (23·9) pg/ml) was significantly lower than in Crohn’s disease (p<0·05 Mann-Whitney) and in normal controls (p<0·02 Mann-Whitney).

**Relation between disease activity, disease site, and TNF-α generation**

A significant positive correlation was found

---

*Note: The text continues with further detailed discussion and analysis not provided in the excerpt.*
between lipopolysaccharide stimulated TNF α generation and disease activity in Crohn’s disease as assessed by a simple index of Crohn’s disease activity \((r=0.67, p<0.001\) Kendall’s rank correlation). When results were analysed by classifying Crohn’s disease according to the extent of the disease, both spontaneous and lipopolysaccharide stimulated TNF α generations in patients with ileocolonic and colonic disease were not significantly different to values in patients with ileal disease alone.

In ulcerative colitis, a significant positive correlation was also found between lipopolysaccharide stimulated TNF α generation and disease activity \((r=0.80, p<0.001\) Kendall’s rank correlation). When results were analysed and classified according to the extent of disease, both spontaneous and lipopolysaccharide stimulated TNF α generations in patients with total colonic involvement were not significantly different to values in patients without total colonic involvement.

**CORRELATIONS OF CYTOKINE GENERATION WITH SERUM C REACTIVE PROTEIN AND α1 ACID GLYCOPROTEIN**

Serum C reactive protein values in the patients with Crohn’s disease varied between 0.5 mg/l and 22.5 mg/l (mean 24.8 mg/l). Those in the patients with ulcerative colitis varied between 0.5 mg/l and 7.2 mg/l (mean 11.7 mg/l).

Statistically significant but weak correlations were found between serum C reactive protein and lipopolysaccharide stimulated IL 1β and TNF α production in Crohn’s disease, and between serum C reactive protein and spontaneous IL 1β production in ulcerative colitis (Table I).

Serum α1 acid glycoprotein concentrations in the patients with Crohn’s disease varied between 98.7 mg/dl and 43.3 mg/dl (mean 202.1 mg/dl). Serum α1 acid glycoprotein values in the patients with ulcerative colitis varied between 69.6 mg/dl and 507.6 mg/dl (mean 167.9 mg/dl).

Statistically significant but weak correlations were found between serum α1 acid glycoprotein and lipopolysaccharide stimulated IL 1β and TNF α production in Crohn’s disease, and between serum α1 acid glycoprotein and spontaneous IL 1β production in ulcerative colitis.

**CORRELATION OF CYTOKINE GENERATION WITH IN VITRO α1 ACID GLYCOPROTEIN SYNTHESIS**

In vitro α1 acid glycoprotein synthesis in response to monocyte conditioned medium from patients with Crohn’s disease, varied between 185.4 ng/ml and 757.7 ng/ml (mean 339.5 ng/ml) for monocytes without lipopolysaccharide, and 231.2 ng/ml and 137.2 ng/ml (mean 489.9 ng/ml) with lipopolysaccharide.

In vitro α1 acid glycoprotein synthesis in response to monocyte conditioned medium from patients with ulcerative colitis, varied between 190.9 ng/ml and 586.7 ng/ml (mean 308.9 ng/ml) for monocytes without lipopolysaccharide, and 241.0 ng/ml and 634.5 ng/ml (mean 436.1 ng/ml) with lipopolysaccharide.

Statistically significant correlations were found between the in vitro generation of α1 acid glycoprotein production in response to conditioned medium and the IL 1β concentration in those medium when the conditioned medium was obtained in the absence but not in the presence of lipopolysaccharide, for both Crohn’s disease and ulcerative colitis (Table II). Correlations with TNF α in the medium were either weaker (in Crohn’s disease) or absent (ulcerative colitis).

**Discussion**

Monocytes-macrophages play a major role in the pathogenesis of an inflammatory response. This study confirms that in active inflammatory bowel disease there is an increased number of circulating monocytes, the precursors of tissue macrophages, and blood with reports that in active disease (both Crohn’s disease and ulcerative colitis) there is an increase in the turnover of peripheral blood monocytes. Activated monocytes also produce cytokines, which are a series of biologically active polypeptides fulfilling the role of inflammatory mediators. The major finding of this study is that there is a difference in the profile of cytokines released by peripheral blood monocytes from patients with Crohn’s disease compared with patients with ulcerative colitis, suggested but not established by previous workers.
We found that lipopolysaccharide stimulated IL 1β generation from peripheral blood monocytes in patients with Crohn’s disease was much greater than in those with ulcerative colitis or normal controls. In active Crohn’s disease, the generation of IL 1β increased dramatically and showed a significant positive correlation with a simple index of Crohn’s disease activity. In ulcerative colitis, IL 1β generation by lipopolysaccharide stimulated monocytes did not differ significantly from values in normal controls and showed only a slight increase in active disease. Thus, monocytes in Crohn’s disease compared with ulcerative colitis show a greater potential for production of this cytokine. With regard to TNF α, lipopolysaccharide stimulated monocytes in Crohn’s disease produced significantly higher values than those in ulcerative colitis. Patients with active Crohn’s disease also released higher levels of lipopolysaccharide stimulated TNF α than healthy controls, although the difference is not statistically significant, and the results therefore suggest that these differences include a relative inability of monocytes from patients with ulcerative colitis to generate TNF α.

Generation of cytokines will lead to inflammation. The local tissues of differing profiles of cytokines in two forms of inflammatory bowel disease lie outside the scope of this report, but in view of the known amplificatory effects of monocyte derived cytokines on other cellular mediators of inflammation, one can speculate that differing elements of the inflammatory response may be amplified in Crohn’s disease compared with ulcerative colitis. In this study, we have examined a remote action of cytokines, their effect on the acute phase protein generation from the liver. Synthesis and secretion of many liver proteins are modulated by cytokines, leading to changes in acute phase protein serum concentrations in inflammation. These changes include a moderate increase in serum concentrations of specific proteins such as α1 acid glycoprotein and proteinase inhibitors like α1 antichymotrypsin and a decrease in albumin. C reactive protein shows a more pronounced response by a two to threefold log increase during this response.

These changes in serum proteins characteristic of an acute phase response occur in inflammatory bowel disease. C reactive protein shows more noticeable changes in Crohn’s disease than in ulcerative colitis. The data reported here accord with the suggestion that a more enhanced acute phase response in Crohn’s disease may reflect differences in the profile of cytokines produced by macrophages from patients with this disorder. This is suggested by the presence of significant though low correlations between IL 1β and TNF α release and with serum C reactive protein and serum α1 acid glycoprotein concentrations in patients with Crohn’s disease. Our studies correlating cytokine generation with the ability of conditioned medium to stimulate α1 acid glycoprotein synthesis in vitro suggest that IL 1β is a major contributor to the control of this particular acute phase reactant in inflammatory bowel disease. Unfortunately the liver cell line we studied does not express C reactive protein.

While suggesting that the greater expression of acute phase response proteins in Crohn’s disease is induced by the cytokines IL 1 and TNF α, this study does not exclude the involvement of other mediators, particularly IL 6 which is recognised to be a major modulator of the acute phase response. Reports on IL 6 production by patients with inflammatory bowel disease have been conflicting. Some observations on IL 6 production by peripheral blood mononuclear cells have reported no significant difference between ulcerative colitis, Crohn’s disease patients, and normal controls. Others report that in Crohn’s disease both IL 6 plasma concentrations and lipopolysaccharide stimulated IL 6 generation by peripheral blood monocytes are raised compared with values in normal controls, but do not show data in ulcerative colitis." There are complex inter-relations between these cytokines, which may act directly or indirectly. Thus IL 1 can induce expression of TNF α and is also a strong inducer of IL 6 release. TNF can also induce release of IL 1, act as a potent stimulus for the production of IL 6, which may then induce the synthesis of acute phase proteins by hepatocytes. Perlmutt et al found that IL 1 and TNF individually increased the synthesis of α1 acid glycoprotein. The results of this study showed in an in vitro study that IL 1β and TNF α lead to a 20 fold increase in α1 acid glycoprotein mRNA in the presence of dexamethasone. IL 6, on the other hand, is a much weaker stimulator of α1 acid glycoprotein synthesis. Each of IL 1β, TNF α and IL 6 has been shown experimentally to modulate C reactive protein production.

The study of acute phase proteins in inflammatory bowel disease is relevant from two points of view. These proteins provide valuable laboratory parameters for assessing disease activity, and this has been the main concern in this study. The physiological relevance of acute phase reactant is not completely understood. A major function of these proteins is to counterbalance indirectly the toxic actions of mediators of inflammation on tissue damage. Since identical numbers of monocytes were employed for each patient in this study, it seems that the differences in cytokine profile reported here between patients with Crohn’s disease and ulcerative colitis reflect an intrinsic, perhaps genetically determined, difference in the ability to produce cytokines rather than a quantitative difference in the number of macrophages activated at the disease site. Although the data obtained were from studying isolated peripheral blood monocytes, relevance to the gut may be inferred since peripheral blood monocytes are precursors of tissue macrophages. Monocytes thus provide an opportunity to study the mononuclear phagocytes cell line before the monocytes migrate from the blood into the bowel mucosa where they became activated. These immunological responses seen in the peripheral blood are events that mirror systemic activation in the gut. Mucosal cytokine production is an important aspect of the mucosal immune system which plays a key role in gut inflammation in both Crohn’s disease and ulcerative colitis. These macrophages do support the immunological basis of the pathogenesis of inflammatory bowel disease. They do not con-
flict with the view that Crohn's disease and ulcerative colitis are part of a spectrum of a single disease process manifesting as different clinical entities, but suggest that the difference in inflammatory events reflects inter alia genetically determined properties of the macrophage series.

This study was supported by a project grant from The National Association for Colitis and Crohn's Disease. The authors wish to thank Dr W A Buurman of University of Limburg, Maasstricht, The Netherlands, for providing murine monoclonal anti-human TNF-α (61E71) and rabbit polyclonal anti-human TNF-α. National Institute for Biological Standards and Control, South Mimms, Potters Bar, Hertfordshire, England, for the gift of recombinant human TNF-α (code 87/850). Gastroenterology registers for their clinical assistance in this study.

Peripheral blood monocyte cytokine production and acute phase response in inflammatory bowel disease.
