Effect of *Escherichia coli* enterotoxins on macromolecular absorption

M Verma, S Majumdar, N K Ganguly, B N S Walia

Abstract

Macromolecular absorption of gliadin, a wheat protein and α-lactalbumin, a milk protein was evaluated in control and *Escherichia coli* enterotoxin (heat-stable, heat-labile, and both heat-stable and heat-labile enterotoxin) treated mice. The peak concentration of gliadin and lactalbumin was two hours and three hours after their ingestion, respectively. There was also a significant increase (p<0.01) in the absorption of both the proteins in all the three toxin treated groups compared with the control group. These results suggest that intestinal permeability and macromolecular absorption changes after *E coli* infection.

(Gut 1994; 35: 1613–1616)

The possible influence of infectious diarrhoea on subsequent food sensitisation in infants is still under investigation. Different animal models of gastrointestinal infection have shown that some types of infection (for example, rotavirus, enteropathogenic *Escherichia coli* strain RDEC-1) might increase intestinal permeability to antigens, but others might not (for example, cholera toxin induced secretory diarrhoea). The intestinal endocytosis of antigenic food proteins is a physiological process, which generally does not lead to pathological immune responses.

In our work, we studied the effect of diarrhoea caused by enterotoxigenic *E coli* (ETEC) on antigen absorption in weanling mice. ETEC strains are important causes of gastrointestinal diseases and especially affect infants throughout the world. It produces two types of toxins heat-labile (LT) enterotoxin and heat-stable (ST) enterotoxin. The first is the activator of adenylate cyclase resulting in an increase in cAMP while the second is the activator of guanylate cyclase resulting in an increase in cGMP. The increased cyclic nucleotide concentration leads to various physiological changes including alteration in the intestinal transport of electrolytes and nutrients.

Our aim in this study was to find out if ETEC enterotoxins affects small intestinal barrier function, which may further affect macromolecular permeability. This was assessed by measuring concentration of gliadin and α-lactalbumin in serum after an oral gliadin and lactalbumin administration as an indication of intestinal macromolecular permeability. ETEC infection in a suckling mouse model provides an excellent system in which to examine this mechanism because of its similarity to disease in human infants.

Methods

TOXIN TREATMENT

Albino mice (2–3 weeks old) were used in the study. Standard ST enterotoxin producing *E coli* strain T83, both ST and LT enterotoxin producing *E coli* strain T83 and LT enterotoxin producing *E coli* strain T100 were obtained from the National Institute of Cholera and Enteric Diseases, Calcutta, WHO Collaborating Centre for Diarrhoeal Diseases Research and Training. The bacteria were grown in tryptic soy broth for 18 hours in a shake culture. The growths were centrifuged for 30 minutes at 4000×g. The supernatants were assayed for the presence of ST or LT enterotoxins. The bioactivity of ST enterotoxin containing supernatant was tested by suckling mouse assay. Briefly, the supernatant was diluted twofold serially and 0.2 ml of each dilution was given intragastrically to a batch of three mice. The last dilution giving a response greater than 0:09 (ratio of gut to remaining body weight) after four hours was considered as the end point and was expressed as the number of mouse units per 0.5 ml. After measuring the concentration, each animal was given intragastrically 0.5 ml of toxin containing 32 mouse units. The animals were killed four hours after the treatment. The presence of ST toxin was also confirmed by enzyme linked immunosorbent assay (ELISA).

Briefly, to each well of the ST enterotoxin coated plates, 50 μl of the supernatant was added. Immediately, 50 μl of antiserum was added to the toxin. After one hour of incubation at 37°C, the plate was washed and 100 μl of horseradish peroxidase conjugated antirabbit immunoglobulin was added. The plate was incubated for one hour at 37°C and washed with phosphate buffered saline. The substrate was added and colour read after 10 minutes. Inhibition of more than 50% of the negative control confirmed the presence of ST enterotoxin.

The presence of LT enterotoxin was confirmed by ELISA as described by Honda *et al* with some modifications. Briefly, the sample was diluted twofold serially and 50 μl of each dilution was added to each well coated with anti heat-labile enterotoxin antibodies. The plate was washed three times with phosphate buffered saline. This was followed by the addition of 50 μl of anti heat-labile enterotoxin conjugated to horseradish...

α lactalbumin was the same as for gliadin except that the α lactalbumin solution was made in TRIS buffer (pH 7.4). The visualisation of immunoreactive gliadin and α lactalbumin was carried out by ELISA and was compared with normal rabbit serum samples. Briefly, the microtitre plates were coated with 100 μl of crude gliadin (2–5 μg/ml 70% ethanol) or α lactalbumin (1 μg/ml) 10 mM TRIS buffer, pH 7.4) and kept overnight at 4°C. Plates were washed three times with phosphate buffered saline containing TWEEN-20 (PBST). To each well 200 μl of PBST containing 1% bovine serum albumin was added and incubated at 37°C for one hour. After washing three times with PBST, to each well 100 μl of the suitably diluted test serum samples (1:2000) were added and the plates were incubated for four hours at 37°C. The plates were washed three times with PBST. One hundred μl of horseradish peroxidase conjugated antirabbit antigliadin or antialactalbumin antibody (1:2000 dilution) was added to each well and kept overnight at 4°C. Plates were again washed three times with PBST. To each well 100 μl of freshly prepared substrate was added and plates were incubated in the dark at 37°C for one hour. The reaction was stopped by an addition of 50 μl/well of 6N H2SO4 and optical density was read at 492 nm by ELISA reader.

**IMMUNISATION PROCEDURE**

Polyclonal antiserum samples were raised against crude gliadin (Sigma) and bovine α lactalbumin (Sigma) in New Zealand white rabbits weighing 2–3 kg according to the method of Friis. A gliadin solution of 1 mg/ml of 100 mM lactic acid was prepared. The rabbits were injected intracutaneously every second week with 200 μl of solution added to an equal volume of Freund’s incomplete adjuvant. The rabbits were bled one week after the sixth and the last injection. The whole schedule for raising antibodies against

Discussion

An increased uptake of macromolecular
protein antigen because of increased permeability has been reported in food allergic subjects. Low concentrations of protein antigens have been detected in the serum of healthy subjects after ingestion of protein. In this study, the effect of diarrhoea caused by ETEC was seen on antigen absorption in weaning mice. Gliadin and lactalbumin were chosen for studying macromolecular absorption in the mouse model as these proteins are unrecognised by the mouse immune system and this avoids the problems of immune clearance through antigen-antibody complex formation.

Byars and Ferraresi suggested that in the rat maximal gut permeability occurred 45 minutes after inducing a local hypersensitivity reaction. In our study we found that the absorption of two macromolecules, gliadin and lactalbumin, achieved peak value at two and three hours respectively after ingestion in both experimental and control groups. There was a significant increase in the absorption of the two proteins in serum infected groups compared with controls. The concentration of proteins in serum samples may result from several functions such as the proteolytic capacity of the gut, the transfer of the antigenic protein from the gut lumen to blood, and the clearance of the protein from blood. It has been reported that acute infection in animals is associated with altered mucosal and systemic immune responses and may promote sensitisation to the allergens present at the epithelium.

There are similar reports for Lumans that show that epithelial alterations resulting from gastrointestinal diseases are responsible for increased passage of food antigens and may induce allergic reactions in certain subjects. This is an indication that changes in intestinal permeability and LT induced diarrhoea are responsible for increased passage of gliadin and lactalbumin. Isolauri et al. have shown that the small intestinal epithelium of rabbits is more permeable to intact proteins at weaning than later in life, which might result from the immaturity of the immune function or differences in the membrane composition. A similar phenomenon has also been shown in human studies. This may also be a reason for increased passage of proteins through small intestinal epithelium as we have used the weaning mouse model in our study and species specific differences in this phenomenon are also known to occur.

The rabbit specific E coli strain RDEC-I infection also leads to a transient increase in the absorption of antigen β-lactoglobulin and intact horseradish peroxidase during peak phase of diarrhoea in rabbits. This infection does not result in disruption of the epithelial layer. Similarly, ETEC producing ST and LT used in this study are not known to invade the enterocytes and yet have caused an increase in macromolecular absorption. The uptake of larger amounts of dietary antigens was also seen in children recovering from acute diarrhoea. The possible influence of infectious diarrhoea on the sensitisation in infants is still under investigation. Acute infections have been shown to cause physiological disturbances and structural modifications of the small intestinal mucosa, which may interfere with the exclusion of foreign protein by the mucosal barrier. The increase in antigenic absorption seen in this study during the acute phase of infection may be paracellular or transcellular resulting from disturbances of the cytoskeletal network as shown in cultured human intestinal epithelial monolayers or resulting from changes in brush border membrane composition or fluidity, or both because of a change in the rate limiting component or change in the barrier in the macromolecular movement. The data reported concerning changes in mucosal handling during acute gastroenteritis are scanty, however, and still controversial. This is probably because of differences between experimental conditions and the causes of the various types of diarrhoeas.

Effect of Escherichia coli enterotoxins on macromolecular absorption.
