Abstract

The cytochrome P450 superfamily of enzymes play a central part in the metabolism of carcinogens and anti-cancer drugs. The expression, cellular localisation, and distribution of different forms of P450 and the functionally associated enzymes epoxide hydrolase and glutathione S-transferases have been investigated in oesophageal cancer and non-neoplastic oesophageal tissue using immunohistochemistry. Expression of the different enzymes was confined to epithelial cells in both non-neoplastic samples and tumour samples except that CYP3A was also identified in mast cells and glutathione S-transferase pi was present in chronic inflammatory cells. CYP1A was present in a small percentage of non-neoplastic samples but both CYP2C and CYP3A were absent. Epoxide hydrolase was present in half of the non-neoplastic samples and the different classes of glutathione S-transferase were present in a low number of samples. In carcinomas CYP1A, CYP3A, epoxide hydrolase, and glutathione S-transferase pi were expressed in at least 60% of samples. The expression of glutathione S-transferases alpha and mu were significantly less in adenocarcinoma compared with squamous carcinoma.

(Gut 1994; 35: 599-603)

Oesophageal cancer is one of the commonest malignancies of the alimentary tract and this tumour is often intrinsically resistant to anti-cancer drugs.1 The geographical distribution of oesophageal cancer has led to the hypothesis that exposure to various toxic environmental or dietary chemicals is an important aetiological factor.3 The principal groups of enzymes responsible for metabolising toxic exogenous chemicals, including anti-cancer drugs and carcinogens, are the cytochromes P450, epoxide hydrolases, and glutathione S-transferases.3-7 Therefore these functionally associated groups of enzymes have important roles in determining the susceptibility of tissues to the toxic effects of xenobiotics and the response of tumours to anti-cancer drugs.8-10

The cytochromes P450 are a multigene superfamily of haem containing enzymes that metabolise both xenobiotics (including carcinogens, mutagens, and therapeutic drugs) and a variety of endogenous compounds (including steroid hormones, arachidonic acid, and fatty acids).11-14 The major xenobiotic metabolising families of P450 are primarily expressed in the liver, although specific forms of P450 are present in particular extrahepatic tissues. The epoxide hydrolases and glutathione S-transferase are two groups of enzymes that participate in the further metabolism of compounds initially metabolised by P450. Epoxide hydrolases participating in xenobiotic metabolism comprise mainly one microsomal and one cytosolic form, which convert potentially toxic epoxides to less reactive dihydriodols, although subsequent reoxidation can lead to the formation of diol-epoxide derivatives, which are often more toxic than the parent compounds.1 The glutathione S-transferases, like the cytochromes P450, are a complex gene family of enzymes, which catalyse the conjugation of reduced glutathione with a variety of electrophilic compounds generally resulting in less toxic, more hydrophilic compounds, which can be more easily excreted.1-4 Like the cytochromes P450 the liver is the main organ in which the glutathione S-transferases are expressed and specific classes of glutathione S-transferases are present in many extrahepatic tissues.

There is little information regarding the presence, distribution, and localisation of different xenobiotic metabolising enzymes in either normal oesophagus or oesophageal tumours and in this study we have investigated the expression of different forms of P450, epoxide hydrolase, and glutathione S-transferase in oesophageal carcinoma and non-neoplastic oesophageal tissue.

Materials and methods

ANTIBODIES
CYP1A and CYP3A were identified using monoclonal antibodies RM314 and HL318 respectively, which have been raised and characterised in our laboratories as described previously. (Individual families and forms of P450 are identified in this study using the designation CYP according to the recent updated nomenclature for cytochrome P450.17 The P450 forms recognised by immunoreactivity in this study are classified according to their sub-family and not identified as being individual members of sub-families as it is not known whether the antibodies are specific to certain sub-family members). CYP2C was identified with a rabbit polyclonal antibody raised in our laboratories against the purified human hepatic form CYP2C9, P450H19. Epoxide hydrolase was recognised using a rabbit polyclonal antibody raised and characterised in our laboratories against a purified preparation of human hepatic microsomal epoxide hydrolase.19 Three major cytoplasmic classes of glutathione S-transferases (alpha, mu, and pi) were identified individually using rabbit polyclonal antibodies obtained from Novoceastra Laboratories, Newcastle upon Tyne. All the antibodies used in this study recognise antigenic epitopes, which are resistant to formalin fixation and wax embedding.
Tissue
Specimens of oesophageal cancer and non-neoplastic oesophagus were obtained from oesophagectomy specimens submitted to the Department of Pathology, University of Aberdeen for diagnostic purposes. All the tissue samples had been fixed in 10% neutral buffered formalin for 24 hours at room temperature and then routinely processed to paraffin wax.

Immunohistochemistry
Formalin fixed wax embedded sections (4 µm) of oesophagus were dewaxed in xylene, rehydrated in alcohol, and then washed sequentially in cold water and 0-05 M TRIS-HCl (pH 7-6) containing 0-15 M sodium chloride (TBS) and then immunostained with various antibodies as described below. Both negative and positive controls were incorporated in the immunohistochemical procedure. Negative controls used in place of the primary antibody were either TBS (control for monoclonal antibodies), or normal rabbit immunoglobulin (control for polyclonal antibodies). Positive controls were sections of normal formalin fixed wax embedded human liver as liver is known to express all the enzymes being studied.

The sections were examined using transmitted light microscopy to establish qualitatively the presence or absence of immunostaining, and its distribution.

Correlations between the expression of the different enzymes were determined using the χ² test with Yates’s correction.

Monoclonal Antibodies
Sections of tissue were incubated for one hour with each of the monoclonal antibodies at the following dilutions: anti-CYP1A (RM3), 1/20 dilution in TBS of a 50% ammonium sulphate precipitate of hybridoma culture supernatant, and anti-CYP3A (HL3) as undiluted hybridoma culture supernatant. Sites of antibody binding were shown using an alkaline phosphatase anti-alkaline phosphatase (APAAP) technique. Rabbit antimouse immunoglobulin (1/100 containing 1% normal human serum, Dako Ltd, High Wycombe, Bucks) and monoclonal APAAP (1/100, Dako) were sequentially applied to the tissue sections for 30 minutes each. Between antibody applications the sections were washed with TBS to remove unbound antibody.

Sites of bound alkaline phosphatase were shown using an enzyme substrate solution containing 3 mg bromo-chloro-indolyl phosphate (Sigma Chemical Co Ltd, Poole, Dorset), 10 mg nitro blue tetrazolium (Sigma), 6 mg sodium azide, and 4 mg levamisole (Sigma) in 10 ml 0-05 M TRIS-HCl buffer (pH 9-0) containing 0-2% magnesium chloride. After incubating the sections for 30 minutes at room temperature, the reaction was stopped by washing the sections in cold tap water. The slides were then air dried and mounted in glycerine jelly.

Polyclonal Antibodies
Anti-CYP2C was applied to tissue sections at a dilution of 1 in 500 (stock solution 20 mg/ml in TBS prepared from the lyophilate of a 50% ammonium sulphate precipitate of immunised rabbit serum). Anti-epoxide hydrolase was applied at a dilution of 1/50 of a stock 20 mg/ml solution, prepared from the lyophilate of a 50% ammonium sulphate precipitate of immunised rabbit serum. Antibodies to the different classes of glutathione S-transferase were applied at the following dilutions of a stock solution (protein concentration 1 mg/ml): glutathione S-transferase alpha 1/100; glutathione S-transferase mu 1/50; glutathione S-transferase pi 1/200. The antibodies were applied to tissue sections for one hour at room temperature, and the sites of bound antibody shown using the APAAP technique. After removal of unbound primary antibody, the sections were incubated with monoclonal mouse antirabbit immunoglobulin (1/100, Dako) for 30 minutes before application of rabbit antirabbit immunoglobulin, APAAP, and alkaline phosphatase substrate solution. The sections were then processed as described above.

Results
Non-neoplastic Oesophagus
Tissue samples obtained from proximal resection margins of 10 oesophagectomy specimens that had been excised for squamous carcinoma were used to investigate the presence of the various enzymes in non-neoplastic oesophagus. These specimens contained all layers of the oesophagus including both squamous epithelial lining and muscularis. CYP1A immunoreactivity was identified in 30% of samples and there was no immunoreactivity for either CYP2C9 or CYP3A in any of the non-neoplastic specimens of oesophagus. Epoxide hydrolase was identified in 50% of the samples and immunoreactivity for

the different classes of glutathione S-transferase alpha, pi, and mu was present in 40, 20, and 20% of the samples respectively. In all cases the positive immunoreactivity was identified with the stratified squamous epithelium with immunostaining being present in all layers of the epithelium. Connective tissue, blood vessels, and smooth muscle showed no immunostaining.

OESOPHAGEAL CANCER
Fifty oesophageal cancers were studied consisting of 25 squamous carcinomas and 25 adenocarcinomas. Based on immunoreactivity, all the carcinomas expressed at least one enzyme and four tumours expressed all seven enzymes (Table I). CYP1A, CYP2C, and CYP3A were identified in 32, 13, and 36 tumours respectively (64, 26, and 72% of the neoplasms respectively). There was widespread expression of epoxide hydrolase with 45 (90%) of tumours showing positive immunoreactivity. Glutathione S-transferase alpha, mu, and pi were present in 27, 20, and 20% of carcinomas respectively (54, 40, and 64% of tumours respectively). Table II summarises the detailed expression of the various xenobiotic metabolising enzymes in the different histological types of oesophageal cancer. The expression of glutathione S-transferase alpha ($\chi^2$, $p=0.005$, 1 degree of freedom) and glutathione S-transferase mu ($\chi^2$, $p=0.009$, 1 degree of freedom) were significantly less in adenocarcinomas compared with squamous carcinomas. The expression of all the other enzymes was similar in the different histological types of oesophageal cancer.

Immunoreactivity for each enzyme was present in the cytoplasm of tumour cells (Figs 1–3), although in a few cases nuclear staining for the different classes of glutathione S-transferases was also seen. The immunoreactivity for each enzyme had a uniform distribution throughout each tumour. In addition, mast cells in normal and carcinoma samples consistently showed strong positive staining for CYP3A while glutathione S-transferase pi immunoreactivity was also identified in chronic inflammatory cells.

Discussion
We have investigated the expression of three specific sub-families of cytochrome P450
(CYP1A, CYP2C, CYP3A) and the functionally associated enzymes epoxide hydrolase and glutathione S-transferase in oesophageal cancer and non-neoplastic oesophagus. The presence in the diet of carcinogens or pro-carcinogens, which can be metabolically activated is an important factor in the development of oesophageal cancer and these compounds are generally metabolised by the xenobiotic metabolising forms of cytochrome P450. The outcome of metabolism in terms of activation (toxicity) or deactivation (detoxification) will depend on the cellular localisation, comparative amount, and activity of the different xenobiotic metabolising enzymes present in a particular tissue. In non-neoplastic oesophagus there was only a low frequency of expression of the enzymes studied and in particular there was no expression of CYP3A. Samples of non-neoplastic oesophagus were obtained from the proximal resection margins of oesophagectomy specimens that contained tumour. Although these specimens displayed no histological abnormality they may not be functionally strictly normal, as they had been obtained from specimens that contained tumour.

Ethically, however, it is not possible to obtain entirely normal oesophagus. A low level of P450 associated activity towards nitroso-methyl-amine has been identified in microsomes prepared from non-neoplastic human oesophageal mucosa although the particular form or forms of P450 contributing to this activity were not identified. Within the human alimentary tract CYP3A is present in a high concentration in the small intestine but either absent or present at a low concentration from colon and it is suggested that a high concentration of CYP3A in the small intestine protects the small intestine from the development of cancer. Conversely, the absence of CYP3A from other sites in the alimentary tract may contribute to the frequent development of malignancy. The failure to detect immunoreactive CYP3A in non-neoplastic oesophagus may support this hypothesis.

There have been no extensive investigations of drug metabolising enzymes in oesophageal neoplasia. The only xenobiotic metabolising enzyme that has been studied in oesophageal malignancy is the pi class of glutathione S-transferase. Both glutathione S-transferase pi mRNA and protein are present in low amounts in non-neoplastic oesophagus but at an increased level in a high proportion of oesophageal squamous carcinomas.

The two different histological groups of oesophageal tumours, namely squamous carcinoma and adenocarcinoma, generally showed a similar pattern of expression of the different enzymes studied with the exception that the glutathione S-transferases alpha and mu were expressed significantly less in adenocarcinoma than squamous carcinoma. The differential expression of these forms of glutathione S-transferase may provide an opportunity clinically for the improved selection of anti-cancer drugs based on knowledge of their metabolism by these forms of glutathione S-transferases. Almost all the tumours displayed positive epoxide hydrolase immunoreactivity and we have previously identified epoxide hydrolase immunoreactivity in a variety of different malignant tumours including hepatic, colon cancer, and breast cancer, which suggests that epoxide hydrolase expression may be a common molecular event in malignancy.

In conclusion, we have found non-neoplastic oesophageal epithelium to be characterised by a low frequency of expression of different xenobiotic metabolising enzymes, with CYP2C and CYP3A being undetectable. In oesophageal cancer the phenotypic expression of the different enzymes was complex with the presence in at least 50% of all tumours of CYP1A and CYP3A, epoxide hydrolase and glutathione S-transferase. The frequent expression of the different xenobiotic metabolising enzymes in oesophageal cancer may contribute to the anti-cancer drug resistance that is characteristic of oesophageal cancer.
