Impairment of intestinal glutathione synthesis in patients with inflammatory bowel disease

B Sido, V Hack, A Hochlehnert, H Lipps, C Herfarth, W Dröge

Abstract

**Background**—Reactive oxygen species contribute to tissue injury in inflammatory bowel disease (IBD). The tripeptide glutathione (GSH) is the most important intracellular antioxidant.

**Aims**—To investigate constituent amino acid plasma levels and the GSH reduct status in different compartments in IBD with emphasis on intestinal GSH synthesis in Crohn’s disease.

**Methods**—Precursor amino acid levels were analysed in plasma and intestinal mucosa. Reduced (rGSH) and oxidised glutathione (GSSG) were determined enzymatically in peripheral blood mononuclear cells (PBMC), red blood cells (RBC), muscle, and in non-inflamed and inflamed ileum mucosa. Mucosal enzyme activity of γ-glutamylcysteine synthetase (γGCS) and γ-glutamyl transferase (γGT) was analysed. Blood of healthy subjects and normal mucosa from a bowel segment resected for tumour growth were used as controls.

**Results**—Abnormally low plasma cysteine and cysteine levels were associated with inflammation in IBD (p<0.01). Decreased rGSH levels were demonstrated in non-inflamed mucosa (p<0.01) and inflamed mucosa (p<0.001) in patients with IBD, while GSSG increased with inflammation (p<0.007) compared with controls. Enzyme activity of γGCS was reduced in non-inflamed mucosa (p<0.01) and, along with γGT, in inflamed mucosa (p<0.01). The GSH content was unchanged in PBMC, RBC, and muscle.

**Conclusions**—Decreased activity of key enzymes involved in GSH synthesis accompanied by a decreased availability of cyst(e)ine for GSH synthesis contribute to mucosal GSH deficiency in IBD. As the impaired mucosal antioxidative capacity may further promote oxidative damage, GSH deficiency might be a target for therapeutic intervention in IBD.

Keywords: Crohn’s disease; ulcerative colitis; glutathione; amino acids; γ-glutamylcysteine synthetase; mucosa

Infiltrating macrophages and neutrophils are abundantly present in inflamed gut in patients with inflammatory bowel disease (IBD). There is a growing body of evidence that these cells expose the inflamed intestine to substantial oxidative stress by production of reactive oxygen species (ROS). Excessive production of ROS could be also demonstrated for circulating phagocytic cells in patients with IBD and was shown to be involved in several models of experimental colitis. The mucosa is endowed with various endogenous antioxidant defence systems to remove ROS resulting from normal metabolism. However, enzyme activities of catalase, superoxide dismutase, and glutathione peroxidase were reported to be low at only 4%, 8%, and 45%, respectively, in healthy colonic mucosa compared with the liver. ROS are highly toxic to cells and oxygen radical formation in excess of physiological amounts may overtax the limited intestinal antioxidant defence system initiating oxidative injury to the gut. Deterioration of antioxidative glutathione metabolism and increased colonic oxidative damage to proteins and DNA in association with impaired enzyme activity of CuZn superoxide dismutase has been reported previously in patients with Crohn’s disease (CD). Efficacy of current standard therapy in IBD was suggested to be related to antioxidant actions: 5-aminosalicylic acid is a highly potent scavenger of ROS and was shown to reduce lipid peroxidation in CD and ulcerative colitis (UC). Preliminary uncontrolled clinical trials showed that CuZn superoxide dismutase may be of benefit in CD and UC. Several classical antioxidants were reportedly effective in reducing ROS production in UC and experimental colitis. Intestinal inflammation induced by administration of an ROS-generating agent in rats could be reversed by supplementation of gluthathione. It has therefore been proposed that IBD results from an imbalance between pro-oxidant and antioxidant mechanisms.

The tripeptide glutathione (L-γ-glutamyl-L-cysteinylglycine, GSH) is the most important intracellular antioxidant. In the presence of ROS reduced GSH (rGSH) is oxidised to glutathione disulphide (GSSG). This reaction is catalysed by GSH peroxidase and reversed by GSH reductase (fig 1). The intestinal GSH content very much depends on GSH synthesis as in vivo administration of a specific inhibitor of γ-glutamylcysteine synthetase (γGCS) results in a rapid decrease of GSH within 30 minutes, ultimately leading to mucosal damage after several days. γGCS, the rate limiting enzyme in GSH synthesis (labelled 2 in fig 1), is controlled via a feedback mechanism by the end product GSH. High intracellular glutamate levels support GSH synthesis as glutamate competes with GSH at the regulatory site of the enzyme γGCS. However, high extracellular glutamate concentrations impair GSH

**METHODS**

**PATIENTS**

Thirty three patients with CD (16 men and 17 women) and 33 patients with UC (19 men and 14 women) with a mean age of 37 (range 19–65) years undergoing resection of inflamed bowel in CD or restorative proctocolectomy with ileal pouch-anal anastomosis in UC were included in the study. None of the patients received parenteral nutrition during a period of three months before the operation. All patients were free of intestinal inflammation postoperatively. IBD was histologically verified by a qualified pathologist. Clinical disease activity was evaluated according to Best for CD patients (CDAI)³⁵ and according to Rachmilewitz for UC patients.³³ In five patients with CD and four with UC the clinical activity index could not be calculated because of pre-existing oostomy. No N-acetyl-L-cysteine was administered throughout the study period. Steroid treatment did not have a significant influence on any of the parameters tested either in blood or tissue, so the data of patients with and without steroids were pooled. Permission to perform the study was obtained from the local ethics committee.

**PROCESSING OF SAMPLES**

Heparinised venous blood was taken from fasting patients preoperatively, and 10 days and three months after the operation and was kept on ice until centrifugation (within 20 minutes). Plasma was deproteínised with 2.5% sulphanilic acid (SSA), incubated for 10 minutes at 4 °C, and subjected to centrifugation (12 000 g, 10 minutes). The supernatant was stored at −80 °C until use. Peripheral blood mononuclear cells (PBMC) were isolated on a Ficoll gradient (Lymphoprep, Nycomed Pharma, Oslo, Norway), lysed in 0.4 ml 2.5% SSA (10 minutes, 4 °C), and centrifuged. The supernatant was stored at −80 °C until assay of GSH. Red blood cells (RBC) from 0.1 ml blood were processed as described for PBMC. For biochemical analysis of mucosa only patients with CD were considered because of the long ischaemia time during proctocolectomy in patients with UC. Resection specimens of 31 patients were available, five of which were from the colon and were therefore not considered. Non-inflamed (n=21) and inflamed mucosa (n=26) was dissected from freshly resected ileum (n=26) of patients with CD, rinsed with iced saline, and snap frozen. Biopsy samples from the rectus abdominis muscle were taken at the beginning of laparotomy of patients with CD (n=19) and snap frozen.

**CONTROLS**

Healthy age and sex matched subjects were used as controls for blood analysis (n=65). Mucosa taken from small bowel of non-cachectic patients undergoing right colectomy for local colonic tumours (n=21) and muscle from patients undergoing laparotomy for various benign non-catabolic diseases (n=18) (abdominal wall hernia (n=3), aortic aneurysm (n=6), hiatal hernia (n=3), benign paranglioma (n=1), gastric ulcer (n=1), mucocent of the appendix (n=1), colon adenoma (n=2), gallstones (n=1)) were used as controls.

**BIOCHEMICAL ANALYSIS**

Deproteinised plasma samples were subjected to amino acid analysis by HPLC (Biotronic LC 3000, Maintal, Germany). Repetitive calibration of amino acid analysis was performed every 7–10 samples within each series using a commercially available amino acid calibration standard (Type P-ANB, Eppendorf/Biotronic, Hamburg, Germany). Additionally, we used an aliquot of a frozen pooled plasma sample as a control sample. Plasma cysteine was determined spectrophotometrically (Ultrospec Plus, Pharmacia, Freiburg, Germany) at 412 nm as acid-soluble thiol using the reagent 5,5′-dithiobis-2-nitrobenzoate (DTNB) as described previously.³⁷ Seven freshly prepared cysteine solutions with different concentrations were used as standards. Linearity of analysis
the level of significance was set at \( p < 0.008 \).\* \( p < 10 \)

analysed by the Student’s \( t \) test for unpaired samples. According to Bonferroni’s correction, completion of inflamed bowel. Values represent means (SE) and were statistically

Data were statistically analysed by the Student’s \( t \) test for unpaired samples including a Bonferroni’s correction.\* \( p < 0.008 \), versus controls (n=65).

was confirmed in each series. Pulverised tissue was homogenised in 2.5% SSA by sonification (Branson Sonifier 250, Branson Ultratronics, Danbury, USA) and centrifuged at 4°C (12 000 g, 10 minutes). For analysis of total GSH (tGSH) in mucosa, muscle, PBMC, and RBC the supernatant was assayed enzymatically as previously described with minor modifications.\textsuperscript{34} Briefly, 10 µl supernatant of the relevant sample was mixed with 90 µl SSA (2.5%), 6 µl triethanolamine, 0.5 ml buffer (0.1 M Na\textsubscript{2}HPO\textsubscript{4}; 5 mM EDTA; pH 7.5) and 0.2 ml DTNB (3 mM) and 1 U yeast glutathione reductase (Sigma, Deisenhofen, Germany). Finally, 0.2 ml NADPH (1 mM) was added and the absorbance recorded at 411 nm. The rate of reaction at 25°C was expressed as the change in absorbance per six minutes. GSSG was determined according to the method of Griffith\textsuperscript{35} after derivatisation of reduced GSH (rGSH) in 0.1 ml supernatant with 2 µl 2-vinylpyridine for 30 minutes at room temperature. Analysis then proceeded as described above. Nine freshly prepared solutions with different concentrations of GSH and GSSG, respectively, were used as standards to calculate the GSH/GSSG concentration in the tissue samples from a linear correlation between absorbance and concentration. The amount of rGSH was calculated as follows: \( r \text{GSH}=r\text{GSH}−2 \times \text{GSSG} \). Protein was determined by the Lowry method.\textsuperscript{36}

For measurement of enzyme activity of \( \gamma \)GCS mucosa samples were sonificated in 0.1 M Tris-HCl buffer (pH 8.0) containing 0.15 M KCl, 20 mM MgCl\textsubscript{2}, and 2 mM Na\textsubscript{2}EDTA. Analysis was performed using a coupled enzyme procedure according to the method of Seelig.\textsuperscript{37} Enzyme activity in the reaction mixture was obtained from the decrease in absorbance of NADH at 340 nm (37°C). For measurement of \( \gamma \)-glutamyl transferase (\( \gamma \)GT) activity mucosa samples were sonificated in 0.4 ml Tris-HCl buffer (0.1 M, pH 8.25) and analysis was performed using a commercially available assay kit (Boehringer Mannheim, Mannheim, Germany). For both enzymes a linear increase in enzyme activity with increasing volumes of tissue homogenate and a linear correlation between absorbance and reaction time has been confirmed in a separate set of experiments. The protein content in the homogenate was determined according to Bradford’s method.\textsuperscript{38}

ANALYSIS OF DATA

Group comparison for statistical analysis was performed using the Student’s \( t \) test for unpaired samples (two tailed) after analysis of variance. The level of significance (\( p < 0.05 \)) was corrected according to Bonferroni to allow for multiple comparisons. Results are presented as mean (SE).

Results

CONSTITUENT AMINO ACIDS OF GSH IN PLASMA AND INTESTINE

The constituent amino acids cysteine and its disulphide cystine, as well as glutamate and glycine were measured in plasma of patients with CD and UC preoperatively, and 10 days and three months postoperatively after resection of inflamed bowel. In both groups of IBD cysteine was found to be significantly decreased before the operation in the presence of intestinal inflammation compared with healthy control subjects (fig 2). Lowest cysteine levels were observed in patients with UC. Cysteine levels rapidly normalised early after removal of...

Inflamed bowel and did not differ from controls three months after the operation in both IBD groups. Interestingly, a separate group of patients with CD without intestinal inflammation, but with manifestation of chronic perianal fistulas, had normal cysteine levels (13.9 (0.7) µM versus 15.3 (0.4) µM in controls; NS). In patients with UC low preoperative cysteine levels were closely correlated with a high clinical activity index (CAI) of Rachmilewitz (r=0.64, p<10⁻⁴; fig 3). Median cysteine levels in controls (CAI 0) and UC patients with low activity (CAI 1–6), moderate activity (CAI 7–12), and high activity (CAI >12) were 15.3, 12.2, 8.9, and 7.9 µM, respectively. Such a correlation could not be established in IBD patients using the CDAI index according to Best. Similarly, the total thiol content in deproteinised plasma in IBD, mainly representing protein sulphydryls, was significantly reduced to the same extent in both CD and UC preoperatively (fig 4). Compared with cysteine, reduction of total thiol levels in plasma persisted early postoperatively but returned to normal values three months after removal of inflamed bowel.

Cystine levels were significantly decreased in both CD and UC patients in the presence of intestinal inflammation (table 1) but rapidly normalised early after the operation. While UC patients maintained high cystine levels three months after restorative proctocolectomy, plasma cystine concentrations dropped again below controls in patients with CD. Glycine levels did not differ from controls in both IBD groups before the operation. However, a long lasting increase was recorded in patients with UC after resection of inflamed bowel, whereas glycine levels initially increased early postoperatively in patients with CD and again reached preoperative values three months later. Glutamate, which is known to inhibit intracellular uptake of cystine competitively, was the only constituent amino acid found to be above control levels before the operation. We observed a 22% higher mean concentration of glutamate in patients with CD compared with controls; the 36% increase seen in patients with UC did not completely return to normal at the end of the observation period.

In contrast to the presented variations in plasma levels of precursor amino acids of GSH, mucosal concentrations of cysteine, glutamate, and glycine consistently tended to be lower in the ileum of patients with CD by 10%, 17%, and 21%, respectively, compared with controls (table 2). Mucosal cysteine concentrations did not parallel the pronounced decrease in plasma levels and mucosal uptake of glutamate was somewhat impaired despite high plasma levels in patients with CD.

INTRACELLULAR GSH CONTENT IN PBMC, RBC, AND MUSCLE

Preoperative plasma analysis revealed a pattern of amino acids which suggests an impairment of GSH synthesis. However, analysing PBMC in the same CD patients we were able to demonstrate that intracellular rGSH and GSSG levels did not differ from controls irrespective of inflammation (table 3). Similar values, although slightly lower, were obtained in patients with UC. rGSH levels were even found to be increased in RBC in patients with CD compared with controls (13.8 (0.9) versus 9.0 (0.5) nmol/mg protein; p<10⁻⁴). This finding was not associated with intestinal inflammation, as results were identical three months after removal of inflamed bowel (15.0 (1.0) nmol/mg protein; p=10⁻⁴ versus controls). A normal redox status of glutathione in both PBMC and RBC, as defined by the ratio rGSH/GSSG, argues against considerable oxidative stress in the blood compartment in IBD.

Similarly, tissue levels of rGSH in the muscle of patients with CD were not decreased despite plasma cyst(e)ine deficiency (11.6 (1.4) versus 13.3 (1.6) nmol/mg protein in controls; NS). As GSSG in muscle was marginally above control values in patients with CD (0.91 (0.16)
versus 0.74 (0.16) nmol/mg protein; NS), the glutathione redox status tended to be decreased in this tissue but did not reach statistical significance (17.1 (2.3) versus 23.7 (2.9) in controls). In summary, deficiency of the sulphur-containing precursor amino acids of GSH in plasma does not result in an impairment of GSH synthesis in blood cells and muscle in IBD, irrespective of the presence or absence of intestinal inflammation.

**GUT MUCOSAL GSH CONTENT**

The finding of unimpaired GSH synthesis in the blood cells and muscle prompted us to investigate the GSH metabolism in inflamed and non-inflamed mucosa of the small bowel. Only patients with CD were considered for these investigations because the large bowel was subject to long ischaemia times during proctocolectomy in patients with UC. In contrast to results obtained in blood cells and muscle, mucosal rGSH was profoundly reduced by 24% and 38% in non-inflamed and inflamed mucosa, respectively (fig 5). Despite the shortage of rGSH, GSSG significantly increased with inflammation. Consequently, the GSH redox status (ratio rGSH/GSSG) dramatically decreased down to 42% in the inflamed ileum. This difference between patients with CD and controls is not simply the consequence of chronic steroid therapy as the GSH redox status in inflamed mucosa of patients receiving steroids (n=13) was 18.1 (1.8) versus 16.0 (1.7) in patients without steroids (n=13) (NS).

**GUT MUCOSAL γGCS ACTIVITY**

γGCS is the rate limiting enzyme in GSH synthesis and activity is negatively regulated via a feedback mechanism by the amount of GSH produced. In CD, however, we observed a profound decrease in γGCS enzyme activity despite GSH deficiency in inflamed and non-inflamed small bowel mucosa (fig 6). Chronic steroid therapy did not improve γGCS enzyme activity which was 95.2 (12.1) nmol/min/mg protein in patients receiving steroids and 83.2 (5.6) nmol/min/mg protein in patients not receiving steroids (NS).

**GUT MUCOSAL γGT ACTIVITY**

γGT is located at the luminal side of the brush border membrane of intestinal epithelial cells. It degrades luminal GSH and GSSG to γ-glutamyl amino acids that are transported to the cell where they are ultimately used for resynthesis of GSH (fig 1). Similarly to γGCS, γGT activity was considerably decreased in inflamed mucosa of the ileum compared with controls and was 17.7 (1.4) and 16.7 (1.6) mU/mg protein in patients with and
without steroids, respectively (NS). In non-inflamed mucosa of patients with CD enzyme activity was intermediate between controls and inflamed tissue (fig 7).

**Discussion**

In this study we present a detailed analysis of gut mucosal GSH synthesis in patients with CD. Decreased activities of enzymes involved in GSH synthesis (γGCS, γGT) predominantly contribute to intestinal GSH deficiency in both non-inflammatory and inflamed ileum. Because the GSH level was shown to be normal or even increased in extraintestinal compartments, decreased availability of the sulphur-containing constituent amino acids of GSH in plasma (but not in the mucosa) seems to be of minor importance. This impaired mucosal antioxidative capacity ultimately increases gut susceptibility to oxidative tissue injury. Despite intestinal γGSH deficiency, the GSSG level increased with inflammation resulting in a pro-oxidant shift of the mucosal redox balance of GSH (γGSH/GSSG) in CD. This could have major implications on intestinal immune functions in IBD as pro-oxidant mechanisms are known to be involved in the activation of the transcription factor NFκB, thereby mediating the transcription of several immunologically relevant cytokines and cell adhesion molecules.19

Cysteine and its disulphide cystine are known to be limiting substrates in GSH biosynthesis23 27 and therefore generate a strong influence on intracellular GSH stores.25 48 Reduced plasma cysteine and cystine levels are not unique to patients with inflammatory bowel disease and could also be demonstrated in other catabolic diseases such as HIV infection13 and advanced malignant tumour growth41 42 in conjunction with a reduction in intracellular GSH levels in PBMC. In patients with IBD cysteine deficiency seems to be a consequence and not a primary mechanism of relapsing inflammation because (1) cysteine and cystine levels rapidly normalise after removal of inflamed bowel in both CD and UC, (2) patients with CD without intestinal inflammation but with manifestations of chronic perianal fistulas have normal cysteine values, (3) UC, which usually involves larger bowel segments, is accompanied by lower cysteine levels than CD, and (4) preoperative cystine levels significantly correlate with the clinical disease activity in patients with UC. Plasma cysteine levels could be decreased due to ongoing inflammation for several reasons. The sulphydryl amino acid cysteine is a potent scavenger of hydroxyl radicals and could be readily consumed due to oxidative stress in the inflamed gut. In support of this explanation is our finding that the decrease in total thiol content in plasma, mainly representing protein sulphydryls, is also associated with inflammation in both CD and UC. Alternatively, hypochlorite that is produced from hydrogen peroxide and chloride via the myeloperoxidase reaction in neutrophils was shown to be present in the mucosa of rectal biopsy samples in patients with IBD.43 The reaction of hypochlorite with ammonia yields monochloramine. Both hypochlorite and monochloramine avidly degrade cysteine44 and could account for cysteine deficiency. Inversely, the therapeutically effective drug 5-aminosalicylic acid is a potent antioxidant,14 inhibits neutrophil production of hypochlorite and monochloramine,44 45 and protects cysteine from degradation by these two toxic compounds.44 Supplementation of cysteine or N-acetyl-l-cysteine might have beneficial effects on disease activity due to its radical scavenging activity and as it helps to replenish intracellular GSH stores as it helps to replenish intracellular GSH stores. Oral application of cysteine has recently been shown to ameliorate tissue injury in experimental colitis.47

Although the pattern of precursor amino acid, as described in the present study, suggests impairment of GSH synthesis in IBD, our results do not argue for overall inhibition of GSH synthesis. Among the compartments analysed we could show a decrease of GSH in the intestine, but not in blood cells and muscle. The reason for the increased GSH content in RBC is presently not known but has also been observed in tumour bearing mice in the presence of decreased plasma cyst(e)ine levels.46 It is unlikely that plasma deficiency of cyst(e)ine is due to avid amino acid uptake into RBC for subsequent GSH synthesis as plasma cyst(e)ine levels normalise postoperatively, although increased GSH levels persist in RBC. In cultured cells cystine is taken up by the membrane amino acid transport system x, that imports cystine in exchange for glutamate.47 In vitro this transport system can be induced by glutathione deficiency or oxidative stress.10 Provided that such a mechanism is active in vivo, induction of the transport system could explain why mucosal levels of cystine were not found to be decreased to the same extent below control levels as were plasma levels and,
