Intestinal failure defined by measurements of intestinal energy and wet weight absorption

P B Jeppesen, P B Mortensen

Abstract

Background and aims—Intestinal failure defined by the minimal energy and wet weight absorption required to avoid home parenteral nutrition (HPN) is not well described. Thus the aim of this study was to identify the minimal level of gut function necessary to avoid parenteral support using objective measurements of intestinal function.

Methods—Energy (bomb calorimetry) and wet weight absorption were measured during 48 hour balance studies in 45 HPN patients with intestinal failure and in 44 non-HPN borderline patients with a short bowel or malabsorption exceeding 2 MJ/day.

Results—In the non-HPN patients, the lower 5% confidence interval of the absorption of energy was 54% of the basal metabolic rate (BMR, the Harris-Benedict equations), equivalent to 4.9 MJ/day. Wet weight absorption was 1.4 kg/day. The HPN patients absorbed less of either or both. The non-HPN patients absorbed 24–86% (range) of the energy and 23–95% of the wet weight. Absorption in the HPN patients ranged from below 0% (net secretion) in patients with very short bowels to 100% absorption of an insufficient oral intake in patients with pseudo-obstruction. Non-HPN patients who absorbed less than half of their intake avoided HPN by hyperphagia (200–400% of BMR equivalent to 10–24 MJ/day, and 3–7 kg/day of wet weight).

Conclusion—Intestinal failure was accurately measured as absorption below 1.4 kg/day of wet weight and 84% of the calculated BMR (depending on weight, sex and age), which is equal to 4.9 MJ/day. Intestinal absorption, expressed as a percentage of intake, did not discriminate between patients with and without intestinal failure, except for patients who absorbed less than 25% of their intake.

Keywords: absorption; intestinal failure; energy; wet weight; short bowel syndrome

Intestinal failure may be defined by the minimal energy and wet weight absorption required to avoid home parenteral nutrition (HPN). Involuntary ingestion below the minimal amount necessary to maintain nutrient and fluid balance, frequently termed oral failure, is seen in patients with pseudo-obstruction and dysmotility syndromes. The principal cause of intestinal failure, however, is a reduction in the functioning gut mass, as seen in short bowel syndrome. In individuals with a healthy intestinal mucosa, a small bowel of 50–70 cm in length provided the colon is intact, or of 100–150 cm in length if resection is accompanied by a colectomy, is required to maintain nutritional integrity and autonomy with enteral feedings and to avoid intestinal failure and dependence on parenteral support. There are, however, exceptions to this rule as intestinal absorptive function rather than length determines the final outcome. Therefore, a functional measure of the intestinal absorptive capacity using bomb calorimetry has been advocated in the management of patients with intestinal insufficiency and failure, but implementation and use in everyday clinical practice has been protracted.

For the objective measurement of intestinal function, we used a short term procedure designed to obtain a high level of patient compliance. Intestinal absorption was evaluated using bomb calorimetry combined with measurement of dietary and faecal weight. The procedure focused on the ability to distinguish between patients who required and those who did not require HPN, thereby defining the minimal gut function needed to avoid intestinal failure in terms of energy and wet weight absorption.

Materials and methods

PATIENTS

Two groups of patients were recruited to the study by mail. The first group comprised 58 patients with intestinal failure (corresponding to approximately 75% of all patients in Denmark receiving or having initiated HPN during the period November 1995 to March 1997). The other group comprised 76 non-HPN patients with intestinal insufficiency, defined as faecal energy excretion of more than 2.0 MJ/day (measured at a previous admission), a remnant small intestine of 200 cm or less (measured peroperatively from the ligament of Treitz) or as having undergone consecutive small intestinal resections exceeding 150 cm.

Forty six of the 58 HPN patients and 45 of the 76 non-HPN patients with intestinal insufficiency consented to participate in the study. One of the non-HPN patients was excluded as she experienced gastroenteritis and vomiting during admission. Also, one HPN patient with protein losing enteropathy was excluded as she

Abbreviations used in this paper: BMR, basal metabolic rate; HPN, home parenteral nutrition.
used her catheter for intravenous calcium supplements only. All HPN patients received parenteral supplements of nutrients or saline at least three times a week. Thus the study comprised 45 HPN and 44 non-HPN patients. None of the patients with inflammatory bowel disease showed evidence of active disease.

STUDY PROTOCOL
Patients were admitted for a period of 2.5 days. On arrival on the first afternoon, patients were given three containers and an electronic precision balance (measuring in grams). Two of the containers were designated for collection of faeces and urine, respectively. In the third container, patients were told to collect a duplicate of their oral intake (both liquid and solid foods). When instructed, patients were told that they could eat what they pleased from breakfast, lunch, and supper buffets, each containing a wide range of food items. The beverages available included water, tea, coffee, milk products, soft drinks, juice, glucose-saline solutions, etc. Sandwiches, biscuits, and beverages were available in the kitchen between meals.

Patients were told to abstain from food between 2200 and 0800 on the day of admission so that faecal excretion during the first 24 hours of the study would not be a reflection of intake prior to the balance period. The study and collection period began at 0800 on the second day of admission and patients were requested to urinate, defecate, or empty their stoma bags. During the next 48 hours, patients collected their faeces, urine, and duplicate diets in the three containers. Before admission, intestinal transit was measured by timing a Brilliant Blue marker from oral administration to its appearance in the faeces of non-HPN patients and HPN patients with a preserved colon. These measurements revealed intestinal transit times of less than 10 hours, except in three HPN patients with oral failure and intestinal dysmotility. Thus the limited duration of intestinal transit indicated that 10 hours of fasting between 2200 and 0800 were sufficient so that the events prior to the balance study did not influence the 48 hour balance period. On retrieval, faeces were deposited on ice, immediately frozen, and kept at −20°C until the samples were analysed.

Patients were interviewed about the composition and volume of parenteral support, and information on daily medicine use was obtained. During admission, patients received their usual parenteral supplements and medication. None of the patients was receiving sodium chloride capsules, but patients drinking a glucose-saline solution were told to place a similar portion in their food container. None of the patients required tube feeding (enteral nutrition).

ETHICS
The study was approved by the Ethics Committee for Medical Research, Copenhagen, Denmark. The procedures followed were in accordance with the ethical standards of the Helsinki Declaration of 1975, as revised in 1983. All patients gave informed consent before entering the study.

STATISTICAL ANALYSIS
Results are expressed as median (25–75% percentiles). Differences between groups were tested using the Mann-Whitney rank sum test and comparisons of frequencies were evaluated by the χ² test or alternatively by Fisher’s exact test using SigmaStat for Windows version 2.0 (copyright 1992–1995, Jandel Corporation, Erkrath, Germany); p<0.05 was considered significant.

RESULTS
PATIENT DEMOGRAPHICS
Patient demographics are shown in table 1. Most patients had Crohn’s disease (37 of 44 in the non-HPN group and 26 of 45 in the HPN group). The two groups had a similar BMR, calculated from information given by the manufacturers. The remnant small intestine was measured peroperatively in 56 patients whereas the length of resection was measured in 31 patients. One of the non-HPN and two of the HPN patients did not have resection of the small intestine. The length of the colon was expressed in terms of percentage of the usual length according to the method of Cummings and colleagues.

ANALYTICAL METHODS
Patient height and fasting body weight were measured on admission. Body composition was measured during or before admission by dual energy x ray absorptiometry (Norland XR-26 DXA densitometer, Norland Corp., Fort Atkinson, Wisconsin, USA). In addition, patient weight six months before admission was obtained from weight curves drawn at ambulatory visits. Basal metabolic rate (BMR) was calculated according to the Harris-Benedict equations using actual body weights.

The weight of the 48 hour oral intake was measured together with faecal and urinary losses. Intestinal wet weight absorption was calculated as equivalent to the difference between the weight of the oral intake and faecal weight. Analyses of the diet and faeces were performed on homogenised, freeze dried samples. Dietary and faecal energy contents were determined by bomb calorimetry using approximately 1 g of freeze dried sample which was combusted in an IKA adiabatic calorimeter (model C 4000 A; IKA-Analysentechnik, Heitersheim, Germany). Intestinal energy absorption was calculated as equivalent to the difference between ingested and excreted energy, and relative absorption as diet-faecal energy/diet energy×100%. The precision of the analytical methods used was demonstrated previously as high, with high reproducibility.

Questionnaires regarding habitual dietary intake of patients were not used. Weight and energy content in parenteral supplements was calculated from information given by the manufacturers. The remnant small intestine was measured peroperatively in 56 patients whereas the length of resection was measured in 31 patients. One of the non-HPN and two of the HPN patients did not have resection of the small intestine. The length of the colon was expressed in terms of percentage of the usual length according to the method of Cummings and colleagues.

The borders between intestinal insufficiency and failure defined by the non-HPN patients resulted in a good distinction between non-HPN and HPN patients. Only five HPN patients were located in the upper right quadrant in the area of non-HPN patients.

**ORAL INTAKE AND PERCENTAGE ABSORBED**

The data presented in fig 1 do not disclose if intestinal failure is due to insufficient absorption of a sufficient amount of food or insufficient intake of food (oral failure). The purpose of figs 2 and 3 was to differentiate between these two different clinical problems, both resulting in intestinal insufficiency or failure.

Figure 2 illustrates the relation between percentage of the diet absorbed (diet-faecal energy/diet energy×100%) and adequacy of dietary intake (dietary energy as a percentage of BMR). The limits of 84% of BMR in fig 1, used to distinguish between intestinal insufficiency and failure, were fitted to the plots from the HPN and non-HPN patients. Several of the HPN patients had an energy intake of less than 84% of BMR and therefore even 100% absorption would not help their dependence on HPN as long as energy intake was that low. Conversely, several of the non-HPN patients...
had compensatory increased energy intake above 200% of BMR (hyperphagia) which meant that they did not require HPN despite absorption of less than 50%. In fact, one patient had a relative energy absorption (diet-faecal energy/diet energy×100%) of only 24% but consumed 22.18 MJ/day and did not receive HPN because of insufficient energy absorption. Four of the remaining five patients were borderline because of insufficient bowel length was disregarded as it was irrelevant to measurements of intestinal function (i.e. to identify the minimal level of gut function necessary to avoid long term parenteral support). Intestinal absorption is often measured as a percentage of intake which (as shown in figs 2 and 3) lacks strict clinical bearing because high absorption of an insufficient amount of food still results in intestinal failure.

The main aim of the study was to define the border between intestinal insufficiency and failure using objective measurements of intestinal function (i.e. to identify the minimal level of gut function necessary to avoid long term parenteral support). Intestinal absorption is often measured as a percentage of intake which (as shown in figs 2 and 3) lacks strict clinical bearing because high absorption of an insufficient amount of food still results in intestinal failure.

The border between intestinal insufficiency and failure was a wet weight absorption of 1.41 kg/day (i.e. patients not able to absorb this quantity would most often need parenteral saline supplements). Most clinicians in charge of these patients would probably agree that 1.5 litres of water seems to be a reasonable minimal amount to compensate for fluids lost from sweat and urine. Because the wet weight absorption includes absorption of approximately 0.13 kg/day of fluid weight, fluid absorption is even less. However, one has to bear in mind the production of water by oxidation of nutrients of approximately 0.03 kg/MJ, thus accounting for approximately 0.27 kg/day in the non-HPN patients.

Surprisingly, the calculated 5% lower confidence level for intestinal sodium absorption was −85 mmol/day in the non-HPN patients, and their median overall balance was −31 mmol/day (corresponding to less than −2 g/day) (table 5). A plausible explanation of the overall negative sodium balance in the non-HPN patients may be a low degree of patient compliance regarding the addition of salt to the solid food containers.

The border between intestinal insufficiency and failure was 84% of BMR. At this level, absorption would have to cover BMR and in addition at least 20–30% to perform daily activities. Even though these patients are known to compensate by low physical activity, it does not explain how they are able to survive at such a low level of energy absorption. Actual BMR was not measured but our data suggest that it was lower in the non-HPN patient closest to the borderline value compared with the estimated BMR calculated by the Harris-Benedict equations. Similar findings have been demonstrated in patients with anorexia nervosa where the resting energy expenditure was reduced to 49–91% of values predicted by the Harris-Benedict equations.11

Figure 1 does not demonstrate oral intake and consequently does not discriminate between patients with oral failure (e.g. pseudo-obstruction) who may or may not absorb a high percentage of the small amount of food they eat, and short bowel patients, who often absorb a low percentage of a large food intake. Thus to describe the spectrum between these two extremes, the percentage of absorption was
plotted against dietary intake for energy (fig 2) and wet weight (fig 3).

Figure 2 clearly demonstrates that many of the non-HPN patients were able to compensate by hyperphagia, as previously described.14 15 Thirty six percent had an energy intake of 200–419% of their BMR. Examining fig 2, it is clear that absorption expressed as a percentage does not help in the classification of a patient before the amount of intake is known, except for those who absorbed less than 25% of their intake. Patients may absorb up to 100% but if energy intake is less than 84% of BMR they will have intestinal failure. Many of these patients had dysmotility disorders combined with pseudo-obstruction. However, if patients who absorb between 100% and 50% for example, could eat a minimum of 84–168% of their calculated BMR, respectively, they may be weaned from HPN and regain intestinal autonomy. Patients with an absorption of 50–25% would correspondingly have to eat at least 168–336% of their BMR every day to avoid HPN. The same principles regarding wet weight rather than energy absorption were considered in fig 3. Hence the position of a given patient, non-HPN or HPN, in figs 2 and 3 illustrates the efforts which have to be made by the patient to discontinue or remain on HPN. Patients whose energy or wet weight absorption is less than 25% are unlikely to be weaned from HPN.

Rodrigues et al investigated energy absorption as a measure of intestinal failure in the short bowel syndrome by bomb calorimetry.4 They measured energy absorption from a liquid meal over a six hour period. A median of 87% (range 82–92%) of the energy was absorbed in a group of five patients with ileostomy. Seven short bowel patients not on HPN absorbed 67% (range 59–78%), and five short bowel patients receiving HPN absorbed 27% (range 2–63%). Messing et al reported a mean coefficient of digestive absorption of energy in five HPN patients of 64% (range 41–85%).16 A median of 71% of energy was absorbed by the non-HPN patients in our study (table 3) but the range was wide (24–86%; fig 2). The HPN patients absorbed 49% of dietary energy (table 3), with values ranging from a net loss of energy of 40% to complete absorption of 100% (fig 2). Therefore, percentage absorption values obtained in different studies are characterised by a wide range, and thus medians are highly dependent on patient selection.

Nightingale et al focused on wet weight absorption in 15 patients with a short residual length of jejunum and no colon.17 In six of the patients who did not require HPN, wet weight absorption was 1.56–2.42 kg/day, closely matching the lower limit in our study. Furthermore, all nine patients who received parenteral supplements were located below the limit suggested.

In summery, patients with intestinal insufficiency who maintained intestinal autonomy and did not depend on parenteral supplements tended to have a wet weight absorption of more than 1.41 kg/day and an energy absorption exceeding 84% of their BMR, as calculated by the Harrison-Benedict equations. Patients with intestinal failure, by definition depending on HPN, tended to absorb less of either weight or energy. Preservation of intestinal autonomy was consistent with a large variation in relative intestinal absorption of 25–100% of either wet weight or energy, as long as oral intake was proportionally increased to meet the total demand, as outlined. Hence the border between intestinal insufficiency and failure was narrow and well defined. Longitudinal studies of the Danish cohort of HPN patients have shown that adaptation occurs in a considerable proportion of patients who are weaned off HPN temporarily or permanently over a period of five years.7 Future prospective studies will assess the value of the measurements of energy and wet weight absorption for predicting if patients with intestinal failure will require lifelong HPN. Furthermore, the short term balance tests may become important educational tools for borderline and selected patients in whom weaning from HPN is desired.

We thank Jette Christiansen, Anne Birgitte Larsen and Bodil Petersen for technical assistance.

Intestinal failure defined by measurements of intestinal energy and wet weight absorption

LETTERS TO THE EDITOR

Differential expression of cyclooxygenase 2 in human colorectal cancer

EDITOR,—We were puzzled by the recent paper by Dimberg and colleagues (Gut 1999;48:730–32) which reported that up-regulation of cyclooxygenase 2 (COX-2) protein expression was prominent in rectal adenocarcinomas compared with that in adenocarcinomas arising from the colon. “Low or undetectable levels of COX-2 protein expression” were demonstrated in 15 of 19 colorectal adenocarcinomas located proximal to the rectum. Overall, up-regulation of COX-2 protein expression was reported in only 56% of colorectal cancers. Previous reports,1–3,7 which include one by the current authors on a not dissimilar case series,1 and two in the joint authorship of the accompanying commentary writer,1,2 have shown consistent up-regulation of COX-2 expression in colorectal adenocarcinomas (in 85–90% of cases) compared with matched normal colon mucosa using different techniques, including northern blot analysis, RT-PCR, western blot analysis, and immunohistochemistry. Furthermore, four of these studies refer to the distribution of adenocarcinomas throughout the colon without showing evidence of differential COX-2 expression between rectal and more proximal tumours.4–6 In the one previous study which analysed COX-2 protein expression in human colorectal cancers by western blot analysis,1 immuno reactive COX-2 was detected in 76% of cases with a 10-fold increase in median tissue COX-2 concentration compared with normal colon mucosa.

In our view, the authors should attempt to explain the discrepancy between their results and previously published data. It is interesting to note that, in the study of Kargman et al., five of six patients taking NSAIDs had low or undetectable COX-2 protein expression.1 Moreover, it has recently been shown to suppress induction of COX-2 mRNA and protein in interleukin-1β and phorbol ester stimulated human endothelial cells and fibroblasts.1 Do the authors have data on NSAID use in their cohort of patients prior to surgery?

Reply

EDITOR,—We agree with Drs Hull and Langman that we found upregulation of COX-2 protein expression in a lower fraction of colorectal cancers (CRC) than previously reported. In part, this may simply be explained by the composition of tumour types within CRC—that is, the number of colorectal versus rectal tumours in our cohort compared with others. In the papers referred to it is difficult to assess the fraction of the different tumour types studied. The differences may also be dependent on the genetic basis for the CRCs studied, which we also have indicated but perhaps not emphasised sufficiently. CRCs with a defective mismatch repair capability, recognised by microsatellite instability (MSI), are accompanied by reduced COX-2 levels.1 At present, we do not know the fraction of MSI type tumours in our series and therefore cannot assess this possibility. An indirect estimate may be achieved since the Min mouse model and human studies provide direct evidence that COX-2 expression may be related to loss of APC function.2 APC and β-catenin mutation analysis of our tumour series shows a good, although not perfect, correlation with COX-2 protein upregulation. Among 18/20 rectal tumours with COX-2 protein upregulation, 12 contained mutations in the APC/β-catenin genes. In contrast, only one of three APC/β-catenin mutated colon tumours revealed COX-2 protein induction and among the remaining 15 non-mutated tumours, two displayed COX-2 protein upregulation. Thus the fraction of APC/β-catenin mutated tumours was also slightly lower (21/38—55%) than previously reported and in accordance with the differential COX-2 induction observed. This may indicate that a larger fraction of CRCs in our cohort are of the MSI type.

Other possibilities for the differences in the fraction of COX-2 upregulation in our tumour series may be the definition of “induction”. In our case, a tumour/normal ratio of femtograms COX-2 per micrograms protein was used. If the opposite COX-2 expression pattern, which may be achieved since the COX-2 gene is normally expressed at low levels,3 we do not know if patients self-administer these types of drugs during the waiting period. We have reviewed the medical records for all CRCs included in the study and found that 7/39 patients were receiving aspirin for cardiovascular protection. Five of these patients had rectal tumours and displayed 7–40-fold induction of COX-2 protein. The two patients with colorectal cancer and aspirin treatment revealed <2- and 10-fold induction, respectively. Thus COX-2 suppression caused by NSAID cannot explain the low prevalence of COX-2 induction in the colorectal tumours. Regulation of COX-2 is not fully understood. Because of the close correlation of upregulated COX-2 with mutations in APC/β-catenin gene it has been hypothesised that there is a regulatory link and that the chemopreventive effect of NSAIDs can be attributed to inhibition of COX-2. However, in a recent paper by He and colleagues it was demonstrated that PPARα (peroxisomal proliferator-activated receptor α) is a target of both APC and NSAIDs resulting in suppressed PPARα activity and promotion of apoptosis. In addition, COX-2 null mouse embryonic fibroblast cells remain resistant to antiproliferative and antineoplastic effects of NSAIDs; hence there seems to be other important mechanisms for NSAID mediated tumour suppression.

The samples in our series were obtained consecutively without any selection. At present, we believe that the observed differential expression of COX-2 may be due to underlying differences in genetic alterations and/or that rectal tumours may represent a biologically distinct subtype of bowel cancer. However, we cannot exclude the possibility that the next 39 CRCs collected will display the opposite COX-2 expression pattern, although we believe this is unlikely.

Proton pump inhibitors for Barrett’s oesophagus

EDITOR,—Recently, the authors of two leading articles, Triafialipoupolos (Gut 2000;46:144–6) and Shepherd (Gut 2000;46:147–49) referred to our paper in Gut.1 We would like to draw attention to the fact that the legend in tables 4 and 5 in our paper should be read as (cm.month), (squares.month), and (%.month) since the variable is the area under the curve (AUC), which is the product of length and surface...
MCP-3 plays an important role in ulcerative patients examined. It would be interesting to might be because of the small number of nately the data on MCP-3 expression in published data).

Reply

EDITOR,—We thank Dr Helwig and colleagues for their interest in our recent paper in which we showed enhanced expression of the C-C chemokine MCP-3 in inflammatory bowel disease mucosa. In the article by Ugucioni and colleagues, we noted their slightly different findings in terms of localisation of MCP-3 expression. Using different techniques (cystatin and paraformaldehyde fixatives, different anti-MCP-3 antibodies) we found consistent expression of MCP-3 in the intestinal epithelium and sporadically in the lamina propria. Ugucioni et al reported MCP-3 expression in the lamina propria. The reason why they did not find MCP-3 expression in the lamina propria remains to be determined. We found that human isolated mast cells are capable of expressing MCP-3 mRNA (unpublished data) which makes them a possible candidate. Other candidates are macrophages and endothelial cells, as reported by Ying and colleagues, who found MCP-3 expression in bronchial biopsies located in these two cell types and in epithelial cells.

In conclusion, we agree with Dr Helwig and colleagues that the role of chemokines in inflammatory bowel disease needs to be evaluated in more detail. Further data are necessary to answer the question of whether or not these alterations in chemokine expression are restricted to specific disorders such as ulcerative colitis or resemble a more general finding associated with any type of intestinal inflammation and host defence mechanisms.

One minute unbuffered urease test: should it be read at 10 minutes?

EDITOR,—The one minute unbuffered rapid urease test, previously described in your journal, was adopted for use at the Royal Melbourne Hospital endoscopy day ward because of its affordability, ease of use, and rapidity. Over time, we had noticed a number of cases where the test had been negative at the one minute mark but later became positive. As we were unsure of whether these “late” positive results represented true or false positives, we decided to run a study to assess the accuracy of the urease test compared with the “gold standard” of histology.

To this end we read and recorded the urease test at one and 10 minutes and compared the results with histological demonstration of Helicobacter pylori on a single antral biopsy. This was carried out on 90 unslected patients undergoing upper gastrointestinal endoscopy for varied indications. Forty one patients were found to have H pylori on histology. The urease test was positive in 20 of these 41 when read at one minute compared with 34 at 10 minutes. There were two false positive results at the one minute mark and four at the 10 minute mark. The performance of the urease test at one and 10 minutes is compared in table 1.

We have demonstrated a significant disparity from published data in the sensitivity of the ultra rapid urease test in our hands. Previous reports have shown a difference between the test results at one minute compared with 15 minutes but this was attributed to the lower initial temperature of the test solution, as it was kept refrigerated until just prior to use. In our ward the test solution is made up in batches and stored at 4°C in the refrigerator but the test tubes are put out at the beginning of the day and thus start off at room temperature. There is evidence to suggest that storage at 4°C for a number of days has no deleterious effects on the performance of the rapid urease test but this factor may explain the poorer performance of the one minute test in our hands.

These factors aside, it is important to point out that we have concluded that the rapid urease test is quite accurate, with sensitivity and specificity comparable with published values for other urease tests, if the reading time is modified to 10 minutes. There are other instances of variability of urease test performance depending on the time interval at which it is read. It may be that, prior to use, these tests need to be validated as conditions may vary from the prescribed ones under which the test was designed.

At 10 minutes the unbuffered urease test still provides results quicker than most rapid urease tests and in fact allows us to inform patients and organise further management for them prior to discharge from the endoscopy suite. Given the overall performance of the test, we are quite happy to plan the treatment of H pylori on the basis of its results. Histology can be reserved for those cases where urease testing is equivocal or other signs such as mucosal abnormalities, are being sought.

Thalidomide treatment of oesophageal ulceration

EDITOR,—I read with interest the case report of thalidomide treatment of oesophageal ulceration treated successfully in a patient with AIDS. The use of thalidomide in Crohn's disease with some success. Idiopathic apha-
thous ulceration may be the first step in the pathogenesis of Crohn's disease—the breach in the mucosal barrier may allow entry of bac-
terial flora and their products to the internal milieu thus setting in train the inflammatory cascade that becomes clinical inflammatory bowel disease. A potent, orally available, and microscopically.

The precise mechanism of thalidomide's effectiveness in oesophageal ulceration remains unclear. The case reported raises the intriguing possibility of more widespread application of this drug in idiopathic gastro-
testinal ulceration. It has already been used in the lower gastrointestinal tract in Crohn's disease and may be an effective and rather than discrete, mimicking lymphoma both macroscopically and microscopically.

2 Hodgson HJF, Bhatti M. Assessment of disease activity in ulcerative colitis and Crohn's dis-

Percutaneous drainage of echinococcal cysts (PAIR—puncture, aspiration, injection, reaspiration: results of a worldwide survey for assessment of its safety and efficacy

EDITOR,—In 1996 a letter (Gut 1996;38:936) about the use of PAIR (puncture, aspiration, injection of a scolicidal agent, reaspiration) raised a criticism of Dr Morris, a leading expert on the treatment of echinococcosis. At the same time the WHO Informal Working Group on Echinococcosis launched a survey to evaluate the status of this procedure. A number of centres around the world known to be active in this field were requested to complete forms for patients treated with PAIR: 765 abdominal cysts, mostly hepatic, treated with this technique were reported from various countries. We report the results of this survey (table 1).

Either needles (18–22 gauge) or catheters (5–9 French gauge), depending on the size and location of the cysts, were used. Scolicidal agents were mainly 20% hypertonic saline and 95% ethanol solution. After aspiration and parasitological control of the fluid, a quantity of scolicidal agent, approxi-
mately equivalent to one third of the amount aspirated, was injected into the cysts and left for a time varying from 5 to 30 minutes, and then reaspirated: only in the cases of Giorgio and colleagues' was the scolicidal agent not reaspirated. In all cases, except for two failures (0.26%) followed by surgery, various degrees of reduction in size (at least 50%) and involution (healing) of the cysts were observed on ultrasound follow up. Anaphylactic shock occurred in four cases (0.52%) and was promptly treated; in one case (0.13%) death ensued notwithstanding re-
susceptive manoeuvres. Recurrences were observed in 12 cases (1.57%) but in eight (1.05%) they were related to an insufficient amount of scolicidal agent (one tenth instead of the average equivalent of one third of the aspirated fluid). Spillage of the fluid in the abdominal cavity was observed in four cases (0.52%) but all patients were receiving prophyaxis with albendazole (seven days to four hours before to 1–4 weeks after) and no peritoneal dissemination occurred. Minor complications (fever, rash, ascites formation, and biliary fistulae) were observed in 105 cases (13.7%); abscess formation was treated with echo guided percutaneous drainage. The follow up is more than five years for 75 cases at the time of presentation of this survey.

These data show that the use of PAIR is widespread and increasing, especially in countries where echinococcosis is endemic. This is also because of its low cost and high efficacy. These data are in accordance with the literature: as of today more than 2400 cysts have been punctured and reported in indexed journals, and success and complica-
tion rates are even lower than those of our survey. PAIR is a safe and effective therapeutic tool; the risk of anaphylaxis during PAIR has been greatly overrated. Complication rates, recurrences, and mortality rates are lower than those of surgery. Accuracy of follow up may be a problem where the popu-
lation is nomadic, but so far no case of perito-
nal dissemination after PAIR has been reported.

| Total cases (cysts) | 765 |
| Follow up > 5 y | 75 |
| Follow up < 5 y | 690 |
| Major complications | 4 (0.52%) (1 death—0.13%) |
| Spillage | 4 (0.52%) (albendazole prophylaxis) |
| Minor complications | 105 (13.7%) |
| Fever (33), rash (14), pain (30), infection of cavity (11), nausea and vomiting (10), intracystic haemorrhage (3), hypotension (2) | 2 (0.26%) |
| Failures | 12 (1.57%) (8 (1.05%) due to an insufficient quantity of scolicide) |

Table 1 Results of the survey on PAIR by the WHO Informal Working Group on Echinococcosis

Use of Doppler ultrasound in Crohn's disease

EDITOR,—We read with interest the article by Maconi et al (Gut 1998;43:654–650). We find it encouraging that other workers are inter-
rested in superior mesenteric artery (SMA) flow concerning Crohn's disease. Our group has been working on the subject for several years. However, we found it surprising to read that “according to the literature” SMA flow does not correlate with disease activity. Firstly, disease activity needs to be defined. The Crohn's disease activity index does not correlate with disease activity in individual patients and the reference standard used by Maconi et al is probably not a reliable indicator for disease activity. Sec-
ondly, it is not correct in our view to correlate the resistive index in one article with mean velocity in another and flow volume in yet another, and make the statement “yielding conflicting results” on page 654. In our opin-
on only flow volume measurements can be used as a reliable indicator.

The fact that Maconi et al did not find a correlation between SMA volume flow and disease activity is probably caused by their choice of refer-
ence standard, as pointed out by Kjeldsen and colleagues, Hodgson and Bhatti, and van Oostayen and colleagues.

There is a need for further studies on PAIR. One of the main issues is to standardise at least some of the points of the various PAIR protocols, under the supervision of the WHO, to compare their efficacy, set up prospective studies, and distribute guidelines to optimise the use of the treatment. Whereas before we felt that the technique was limited to a narrow group of patients, today we believe that PAIR is not only an alternative but an effective first choice diagnostic and therapeutic tool in the management of human cystic echinococcosis.

CORRESPONDENCE

EDITOR,—I remain unconvinced of two basic points. First, PAIR is a diagnostic and therapeutic tool in the management of human cystic echinococcosis. According to our recent data, the recurrence rate of PAIR is now less than surgery is either simplistic or deliberately misleading. Filice et al state that 75 patients (or is it cysts?) have been followed up for five years—the type and frequency of follow up is not stated and this is really critical. Careful ultrasonic follow up can demonstrate recurrence following surgery in up to 22% of patients3 but one can equally well quote surgical series with poor follow up with low recurrence rates; to claim that recurrence rates are lower following PAIR when the type and completeness of follow up is not even stated in scientifically quite invalid.

That cysts shrink (variably) following PAIR is reported, but what does this mean—is this synonymous with parasite death? I doubt it! Only one PAIR study reported reappraisal at three days post-PAIR and 2/14 patients had live protoscolices.

The use of albendazole for four hours to seven days prior to and for 1–4 weeks after PAIR is a clear attempt to reduce the risk of recurrence. In my original laboratory work it took of the order of 30 days to be effective and in humans, two patients who received albendazole for one and three weeks, respectively, prior to operation had viable protoscolices4. The use of post-spillage therapy to reduce the risk of implantation has been variably effective in animal models of spillage.5

We have made at least some attempt to define the minimum length of such therapy.7 The over representation of a poor presentation of data, which I suspect is of even poorer quality, does not improve my view of PAIR, or of the WHO working group. I am quite prepared to accept that PAIR may be the best available option in some areas of the world where surgery and perioperative care are compromised by economic factors or lack of experience, but its comparison with the best available option in some areas of the world where surgery and perioperative care are compromised is not even stated in scientifically quite invalid.

Replies

EDITOR,—I remain unconvinced of two basic things: it is (PAIR) safe and is it effective? With regard to safety these are three issues:

(a) Anaphylaxis. This occurred in four patients after PAIR in the current report and caused one death. An additional three patients became hypotensive and 14 developed a rash. I believe this is a higher risk than surgery should entail.

(b) Dissemination. The peritoneal dissemination of hydatid disease due to needling a liver cyst will take some time to present—how long? In a series of patients with peritoneal hydatid disease, presentation did not occur until nine years (5–14 years) after surgery.8 Current follow up of PAIR does not address this issue. Spillage of hydatid material only causes recurrence in approximately 30% of patients.9 Peritoneal hydatid can be a serious or fatal problem.3

(c) Sclerosis cholangitis. A significant proportion of hydatid cysts communicate with the biliary tree; use of scolicidal agents even at open surgery has caused sclerosing cholangitis. The surgeon has the opportunity of identifying and protecting such a communication prior to the use of scolicide.

Is it effective? The comment that the recurrence rate of PAIR is now less than surgery is either simplistic or deliberately misleading. Filice et al state that 75 patients (or is it cysts?) have been followed up for five years—the type and frequency of follow up is not stated and this is really critical. Careful ultrasonic follow up can demonstrate recurrence following surgery in up to 22% of patients but one can equally well quote surgical series with poor follow up with low recurrence rates; to claim that recurrence rates are lower following PAIR when the type and completeness of follow up is not even stated in scientifically quite invalid.

That cysts shrink (variably) following PAIR is reported, but what does this mean—is this synonymous with parasite death? I doubt it! Only one PAIR study reported reappraisal at three days post-PAIR and 2/14 patients had live protoscolices.

The use of albendazole for four hours to seven days prior to and for 1–4 weeks after PAIR is a clear attempt to reduce the risk of recurrence. In my original laboratory work it took of the order of 30 days to be effective and in humans, two patients who received albendazole for one and three weeks, respectively, prior to operation had viable protoscolices. The use of post-spillage therapy to reduce the risk of implantation has been variably effective in animal models of spillage.

We have made at least some attempt to define the minimum length of such therapy. The over representation of a poor presentation of data, which I suspect is of even poorer quality, does not improve my view of PAIR, or of the WHO working group. I am quite prepared to accept that PAIR may be the best available option in some areas of the world where surgery and perioperative care are compromised by economic factors or lack of experience, but its comparison with the best available option in some areas of the world where surgery and perioperative care are compromised is not even stated in scientifically quite invalid.

BOOK REVIEWS

I should say immediately that this is an excellent book. For those interested in mucosal immunology, little more is necessary. It comprises an up to date and comprehensive series of 13 reviews by scientists who have made important contributions to the field. I am very pleased to have a copy; it will be extremely useful.

Clinical gastroenterologists spend a great deal of their time battling with mucosal T cells, yet because these cells are too small to be seen with an endoscope (in any case they would be obscured in exudate or by the epithelial cell layer) and are difficult to stain on formalin fixed histopathology sections, they are rarely observed. The weapons used against these adversaries are principally nonspecific drugs which have, obviously, worked if the patient gets better.

Thus, although it is tempting to take Sherlock Holmes’ attitude and, when told by Watson that the earth revolves around the sun, feel that the mind is an attic that when filled with details of astronomy (or mucosal immunology), will leave no space for the more useful minutiae of Egyptian tobacco (or the indications for the latest (biliary expanding metal stent). But Holmes liked to have a comprehensive grasp of the background of the case, and I believe that he would not have missed a chance to study this book had he been a contemporary gastroenterologist.

The language of the book may be a problem for the non-immunologist, particularly if one’s medical school notes stop at the Bursa of Fabricius. This is certainly state of the art immunology, but is directed at clinicians as well as scientists. Therefore, if you want to know more about current developments in inflammatory bowel disease, coeliac disease, or HIV, or you are just curious about what some of those cells that you see in biopsy samples might be doing, I strongly recommend that you invest some money in a copy of this book and some effort in reading it. Furthermore, I suggest beginning with the chapter on “Mouse models of gut inflammation”—such models may not be identical to human inflammatory bowel disease, but at least they give us an opportunity to understand it.

And if you can’t remember what CD25 is? Get a copy of Immunobiology by Janeway and Travers (3rd Edition; Current Biology Ltd, 1997); this is another excellent book where no previous knowledge is assumed. There you are—two rave reviews—or three if you count A Study in Scarlet.

A. J. S. MacPherson

This is a collection of work by 31 predominantly North American, European, and Japanese gastroenterologists, digestive surgeons,
and radiologists. The list of authors includes leading figures in the field of digestive endosonography, namely those who took part in the development of the first pieces of equipment and who described the basic principles of endoscopic ultrasound, and the new generation of practitioners responsible for the most recent developments in this area, particularly the introduction of the endoscopic ultrasound guided puncture. This collective work is complete and exhaustive; it is in large format and divided into seven sections, supplemented by a very detailed and helpful index.

The book is a popular work and the teaching material it contains is very practical, detailed, and useful for beginners. However, the book relies on the experiences of the expert authors, which I find to be of much less interest. Much of their experience is now out of date. Endoscopic images are grouped at the beginning of the book and reproduced in black and white in appropriate chapters.

In summary, this is a book of high quality work with some good illustrations. The division between the technical sections and those on anatomy is well balanced, which is original to this type of work and is very informative. A number of chapters are extremely useful, particularly those on the linear array endoscope and portal hypertension. Some areas covered have less impact, particularly those concerned with the authors’ different experiences of gastrointestinal and retroperitoneal pathology. Often, gastrointestinal endosonography is poorly covered; biliary endosonoscopy is not discussed at all. This significant gap is an invitation to other authors to publish a work dedicated to biliopancreatic endosonoscopy, a useful supplement to the work of doctors van Dam and Sivak.

L. PALAZZO

It seems almost unimaginable to me that, somewhere out there, exists a clinical gastroenterologist who would not want to own this book. Maybe I was destined to be the curator of the book review section of Gut just so that a review copy of this majestic atlas might come across my desk. What little effort it is to find words of praise for this tour de force of gastrointestinal radiology.

In one of the most delightfully understated introductions of the century, Roddy MacSween writes that ‘‘this volume brings credit to radiology as a discipline’’. Oh yes indeed, and so very much more! Dr Vallance and selected colleagues have produced a book in which every single illustration (and there are many hundreds) is crystal clear. There are many radiological texts that are comprehensive, and there is a lesser number in which the pictures are clear. There are few books indeed in which every picture credibly reveals the pathology in a totally convincing manner. I do not believe there is single illustration in this book that is not of a high order, and this applies equally to plain radiographs, barium studies, ultrasound, CT, MRI, angiography, or EUS.

Despite its visual excellence, there are idiosyncrasies. Quite what CT and MRI scans of parotid tumours are doing in a book of GI radiology quite escapes this reviewer. Less satisfactory still are some of the mini essays introducing each system. I suspect most readers will not be particularly enlightened by the two page essays that introduce each organ—too brief to say any more than most clinicians must surely know already. For example, who would learn much from: ‘‘Ileostomy enema. The distal small bowel may be examined satisfactorily in patients with an ileostomy by retrograde infusion of barium with or without air, introduced by Foley catheter.’’

The essays are weak, but the legends and the figures are of exceptional quality. A well constructed legend obviates the need for arrows, or other marks, on the radiograph. In this atlas, arrows do appear from time to time, but they are not intrusive. I suggest that this atlas might very well be added to the extremely short list of books that every gastroenterologist should own.

- An outline of the proposed content of the lecture, including title
- A written statement confirming that all or a substantial part of the work has been personally conducted in the UK or Eire.

An applicant need not be a member of the Society. The recipient will be required to deliver a 20 minute lecture at the Annual meeting of the Society in Glasgow in March 2001. Applications (TWENTY COPIES) should be made to the Endoscopy Section Secretary, British Society of Gastroenterology, 3 St Andrews Place, London NW1 4LB by 1 December 2000.

CORRECTIONS

An error occurred in the paper by Fisher et al (Gut 2000;46:534–539). Levels of protein C, protein S, antithrombin and factor VII were (by definition) too high throughout the manuscript. In the Methods section, normal ranges for protein C, protein S, antithrombin and factor VII should have read 66–122 U/dl, 68–146 U/dl, 75–140 U/dl, and 50–150 U/dl. Similar corrections should apply throughout the Results section and in the legend to figure 1. This was an editorial error for which Gut apologises.

An error occurred in figure 1 in the paper by Jeppesen and Mortensen (Gut 2000;46:701–706). The correct figure is published below. The correct figure appears on the Gut website (www.gutjnl.com) and thus diverges from the print version of the May issue. We apologise for any confusion this error may have caused.
