Bifidobacterium strains from resident infant human gastrointestinal microflora exert antimicrobial activity

V Liévin, I Peiffer, S Hudault, F Rochat, D Brassart, J-R Neeser, A L Servin

Abstract

Background and aims—The gastrointestinal microflora exerts a barrier effect against enteropathogens. The aim of this study was to examine if bifidobacteria, a major species of the human colonic microflora, participates in the barrier effect by developing antimicrobial activity against enterovirulent bacteria.

Methods—Antibacterial activity was examined in vitro against a wide range of Gram negative and Gram positive pathogens. Inhibition of Salmonella typhimurium SL1334 cell association and cell invasion was investigated in vitro using Caco-2 cells. Colonisation of the gastrointestinal tract in vivo by bifidobacteria was examined in axenic C3/Heloujco mice. Antimicrobial activity was examined in vivo in axenic C3/Heloujco mice infected by the lethal S typhimurium C5 strain.

Results—Fourteen human bifidobacterium strains isolated from infant stools were examined for antimicrobial activity. Two strains (CA1 and F9) expressed antagonistic activity against pathogens in vitro, inhibited cell entry, and killed intracellular S typhimurium SL1334 in Caco-2 cells. An antibacterial component(s) produced by CA1 and F9 was found to be a lipophilic molecule(s) with a molecular weight of less than 3500. In the axenic C3/Heloujco mice, CA1 and F9 strains colonised the intestinal tract and protected mice against S typhimurium C5 lethal infection.

Conclusion—Several bifidobacterium strains from resident infant human gastrointestinal microflora exert antimicrobial activity, suggesting that they could participate in the “barrier effect” produced by the indigenous microflora.

Keywords: bifidobacteria; infant microflora; gastrointestinal infection; antimicrobial; microbial infection; intestinal cells

The normal flora of the human gastrointestinal tract contains many diverse populations of bacteria which play an essential role in the development and well being of the host. In particular, the intestinal microflora exerts a protective role against pathogens. Knowledge of the predominant genera and species, and their levels and biochemical activity are essential to understand the microbial ecology of the gastrointestinal tract. A long established but controversial concept is that of beneficial species. Among the species present in the human intestinal microflora, several reports have emphasised the role of bifidobacteria. Bifidobacteria are anaerobic, rod shaped, Gram positive bacteria that are normal inhabitants of the human colon constituting a predominant part of the anaerobic flora. Indeed, bifidobacteria are the predominant intestinal organisms of breast fed infants. Adults also carry bifidobacteria in their colonic flora. The composition of the intestinal human gut microflora can be modulated by live microbial feed supplements. Moreover, prebiotics—that is, non-digestible food ingredients—can also modify the intestinal microflora and in particular increase the level of bifidobacteria. A role for bifidobacteria in host resistance to infection has been proposed. In vitro laboratory and animal studies have shown that bifidobacteria exert antagonistic activity against pathogens. Moreover, it is recognised that the antimicrobial properties of bifidobacteria could contribute to the protection that breast feeding provides against gut infection. To gain further insight into the mechanism by which resident bifidobacteria of the human microflora could exert a protective role against pathogens, we examined the antibacterial activity of bifidobacterium strains isolated from infant stools.

Materials and methods

BACTERIA

Bifidobacterium strains were isolated from infant human stools. A nut sized piece of faeces was placed in a sterile tube. For optimal survival of the extremely sensitive anaerobic bacteria, the samples had to be treated within 30 minutes after emission. Otherwise, the samples were kept in an anaerobic jar until analysis (maximum of 10 hours). Isolation was conducted in an anaerobic Freter chamber. Firstly, a 10-fold dilution was performed in a pre-reduced Ringer solution with 10% glycerol. The sample was then aliquoted and a safety stock was prepared for freezing in liquid nitrogen. Serial dilutions were prepared and 100 μl of each dilution were plated on agar plates prepared with a medium selective for bifidobacteria. Plates were incubated for two days under anaerobic conditions. Bifidobacterium colonies were round and white. However, other bacteria such as lactobacilli can grow on

Abbreviations used in this paper: SCS, spent culture supernatant; PBS, phosphate buffered saline; cfu, colony forming units; MRS broth, De Man, Rogosa, Sharpe broth; TSA, tryptic soy agar.
this medium. To differentiate bifidobacteria from other colonies, it was necessary to examine each isolated colony by light microscopy. The selective medium used is particularly adapted to promote the typical Y shape of bifidobacteria. Likely colonies of bifidobacteria were isolated and grown again on the same medium for amplification, further identification, and conservation. Final identification was made using API tests (Api ID 32A, Bio Mérieux, Marcy l'Etoile, France). Colonies thus identified were extracted from the agar plates and homogenised in BHI medium (Oxoid) containing 40% glycerol (w/v). Aliquots were transferred in cryotubes. These tubes were frozen and kept in liquid nitrogen.

Before use, bifidobacteria were grown under anaerobic conditions (Gaspack H2+CO2) in De Man, Rogosa, Sharpe (MRS) broth (Biokar, Paris France). Cells were centrifuged at 5500 g for 30 minutes at 4°C. Centrifuged SCS was passed through a sterile 0.22 µm filter unit Millex GS (Millipore, Molsheim, France). Filtered SCS was verified for the absence of bifidobacteria by plating on tryptic soy agar. A pH ranging from 4 to 4.5 was observed for different bifidobacteria-SCS; consequently, the pH of bifidobacteria-SCS was adjusted to 4.5 with HCl for all experiments. Concentrated bifidobacteria-SCS was obtained by freeze drying (2.5-fold concentrate, pH 4.5).

Salmonella typhimurium SL 1344 was a gift from BAD Stocker (Stanford, California, USA),25 S typhimurium C5 was provided by MY Popoff (Institut Pasteur, Paris, France),25 Listeria monocytogenes EGD [HLY] was provided by J L Gaillard (Faculté Necker-Enfants Malades, Paris, France),25 Escherichia coli C1845 was a gift from S Bilge (University of Washington, Seattle, USA),25 and Shigella flexneri M90T was provided by P Sansonetti (Institut Pasteur, Paris).25 Clostridium difficile Cd 79-685 was isolated from a stool sample of a patient with antibiotic associated pseudomembranous colitis (Institut de Bactériologie, Strasbourg, France).25 Staphylococcus aureus, Streptococcus D, Pseudomonas aeruginosa, and Klebsiella pneumoniae were stock clinical isolates from the microbiological laboratory of the Faculté de Pharmacie Paris XI, Chàtenay-Malabry, France.

ANTIMICROBIAL TESTING
Antimicrobial activity of bifidobacteria was examined as previously described.30–32 As indicator strain, S typhimurium SL1344 was grown overnight for 18 hours at 37°C in Luria broth. To obtain mid-logarithmic phase organisms, 10 ml of fresh trypticase soy broth were inoculated with 200 µl of cultured Luria broth and incubated for an additional three hours at 37°C. The bacteria were centrifuged at 5500 g for five minutes at 4°C, washed once with phosphate buffered saline (PBS), and resuspended in PBS. S typhimurium were counted and a volume containing 105 colony forming units (cfu)/ml was used to determine the activity of bifidobacteria-SCS. Colony count assays were performed by incubating 1 ml of PBS containing S typhimurium (108 cfu/ml) with 1 ml of bifidobacteria SCS at 37°C. At predetermined intervals, aliquots were removed, serially diluted, and plated on trypticase soy agar (TSA) to determine bacterial colony counts.

CHARACTERISTICS OF BIFIDOBACTERIA-SCS

ANTIMICROBIAL ACTIVITY
The remaining antimicrobial activity against S typhimurium SL1344 in both treated samples was determined by the antimicrobial assay described above.

Ammonium sulphate precipitation was conducted by adding solid ammonium sulphate to the bifidobacteria-SCS with stirring until the solution reached 60% saturation. This solution was kept at 4°C overnight to allow complete precipitation of the protein and then centrifuged at 10 000 g for 15 minutes. Activity was determined in the pellet resuspended in sterile PBS.

The lipophilic fraction was extracted from bifidobacteria-SCS with chloroform-methanol (1:1, vol/vol). The resulting chloroform layer was dried under nitrogen stream and the lipophilic fraction was resuspended in sterile PBS to test activity.

Estimation of molecular weight was conducted by dialysis of the bifidobacteria-SCS with Spectra/Per membrane tubing (The Spectrum Companies, Gardena, California, USA), with a molecular weight cut off of 3500.

CELL CULTURE
We used the cultured human colonic adenocarcinoma Caco-2 cell line,25 which spontaneously differentiates in culture expressing characteristics of the mature enterocyte of the small intestine. Caco-2 cells were routinely grown in Dulbecco modified Eagle's minimal essential medium (25 mM glucose) (Eurobio, Paris, France), supplemented with 20% fetal calf serum (Boehringer, Mannheim, Germany) and 1% non-essential amino acids. Cells were seeded in six well Corning tissue culture plates (Corning Glass Works, Corning, New York, USA) at a concentration of 104 cells/cm2. For maintenance purposes, cells were passaged weekly using 0.25% trypsin in Ca2+ Mg2+ free PBS containing 0.53 mM EDTA. Maintenance of cells and all experiments were carried out at 37°C in a 10% CO2/90% air atmosphere. Differentiated cells were used for adherence assays at late post-confluence (15 days in culture).

INFECTION OF CULTURED CELLS BY S TYPHIMURIUM
The cell infection assay was conducted as previously reported.17 30–32 35 36 Briefly, prior to infection, the Caco-2 monolayers were washed twice with PBS. S typhimurium SL1344 were suspended in the culture medium and a total of 2 ml (108 or 107 cfu/ml as mentioned) of this suspension were added to each well of the tissue culture plate. The plates were incubated for one hour at 37°C in 10% CO2/90% air and then washed three times with sterile PBS. S typhimurium internalisation was determined by quantitative determination of bacteria

www.gutjnl.com
located within the infected monolayers using the aminoglycoside antibiotic assay. After incubation, monolayers were washed twice with sterile PBS and incubated for one hour in a medium containing gentamicin 50 µg/ml. Bacteria that adhered to the cell brush border were rapidly killed, whereas those located within the cells were not. The infected monolayers were washed with PBS to remove the killed bacteria. The monolayers were lysed with sterilised H2O. Washed with PBS to remove the killed bacteria. The infected monolayers were rapidly killed, whereas those located within the cells were not. The infected monolayers were washed with PBS to remove the killed bacteria. The monolayers were lysed with sterilised H2O.

Appropriate dilutions were plated on trypticase soy agar to determine the number of viable intracellular bacteria by bacterial colony counts. Each assay was conducted in triplicate with three successive passages of Caco-2 cells. Inhibition of S typhimurium SL1344 invasion within Caco-2 cell by MRS or bifidobacteria-SCS was examined as previously described.17 30 31 35 36 Before cell infection, the pathogen (10⁷ cfu/ml) was preincubated with MRS or bifidobacteria-SCS (2.5-fold concentrated and adjusted to pH 4.5) for one hour at 37°C. After centrifugation (5500 g, 10 minutes at 4°C), bacteria were washed with PBS and resuspended in Caco-2 cell culture medium. Contact between the cells and the MRS or SCS treated S typhimurium was for one hour at 37°C. Determination of viable intracellular S typhimurium was conducted as described above.

Activity of MRS or bifidobacteria-SCS against intracellular S typhimurium was determined using the preinfected Caco-2 as previously described.31 Cells were infected by S typhimurium SL1344 (10⁶ cfu/ml) for one hour at 37°C. After washing the infected cells with PBS twice, the extracellular bacteria were killed by gentamicin (50 µg/ml, one hour at 37°C) and cells were washed with PBS to remove the killed bacteria. MRS or bifidobacteria-SCS (2.5-fold concentrated and adjusted at pH 4.5) were added apically to the preinfected cells and incubated for one hour at 37°C. Determination of viable intracellular S typhimurium was conducted as described above.

**ACTIVITY OF BIFIDOBACTERIUM STRAINS AGAINST S TYPHIMURIUM C5 INFECTION IN AXENIC MICE**

Antimicrobial activity of bifidobacterium strains was examined in vivo using the protocol previously used to determine anti-salmonella activity of Lactobacillus in germ free mice.32 36 S typhimurium C5 strain was grown in Luria broth for 18 hours at 37°C. The culture was harvested in PBS. Viable bacteria were numbered after plating suitable dilutions on TSA and incubation at 37°C for 18 hours. Incubation of S typhimurium C5 in germfree or monoassociated mice was as follows: a single dose of 2×10⁸ cfu/mouse was given to the animals, deprived of water since the day before, in bottled water. Monoaxenic mice were germinfree C3H/He/Oujco mice (six mice per group) inoculated with bifidobacterium strains as a single dose of a 100-fold diluted fresh culture in bottled water, one week before challenge C5.

**DETERMINATION OF BIFIDOBACTERIA COLONISING THE INTESTINAL TRACT OF MONOXENIC MICE**

Germ free animals (Iffa Credo, L’Arbresle 69, France) were adult female C3H/He/Oujco mice of 7–8 weeks of age. They were housed and fed in accordance with the relevant national legislation. Germ free mice (Cesal, Orléans, France) were reared in Trexler type isolators fitted with a rapid transfer system (La Calhène, Vélizy Villacoublay, France). They were fed ad libitum a commercial diet RO3 (UAR, Vilmemoisson/Orge, France) irradiated at 40 kGy and autoclaved demineralised water, or a non-irradiated diet, respectively.

Bifidobacterium strains were inoculated in germ free C3H/He/Oujco mice (six mice per group) as a single dose of a 100-fold diluted fresh culture in bottled water. One week before challenge, monoassociated gnotobiotic mice were killed by cervical elongation. The contents of the stomach, each part of the small intestine (the small intestine was separated into three equal parts: SI-1, SI-2, and SI-3) and the caecum were sampled. To determine the level of bifidobacteria associated with the tissue in different parts of the gastrointestinal tract, the stomach, the three parts of the small intestine, colon, and caecum were sampled and washed eight times with sterilised PBS. The tissues were weighed, mixed with 1 ml of PBS by Ultraturax for two minutes, and then diluted 10-fold. Counts of bifidobacteria were obtained by plating 0.1 ml of each 10-fold serial dilution on MRS agar pH 5.4. The plates were incubated at 37°C for 48 hours under anaerobic conditions (Gaspack H2+CO2). Bacterial counts of bifidobacteria are given per gram of content or tissue.

**Results**

**ANTIBACTERIAL ACTIVITY IN VITRO**

Fourteen human bifidobacterium strains isolated from infant stools were examined for their antimicrobial activity (table 1). For this purpose, the S typhimurium strain SL1344 was previously used to determine anti-salmonella activity of Lactobacillus in germ free mice.32 36

Table 5 Distribution of infant bifidobacterium colonising the intestine of germ free C3H/He/Oujco mice

Experimental conditions are described in materials and methods.

Levels of bifidobacteria colonising different parts of the intestine in germ free C3H/He/Oujco mice inoculated with a single dose of human infant or adult bifidobacteria. Population of bifidobacteria was determined seven days post-administration in the intestinal content and in washed tissue. Results are presented as cfu/g of content or cfu/g of tissue (mean (SEM)) obtained from 5–6 mice per group.

*Small intestine (SI) was separated into three equal parts: SI-1, SI-2, and SI-3.

Discussion

Important to human health, the gastrointestinal microflora contains a substantial and complex collection of microorganisms forming a biologically pivotal component of the host body. This microflora is composed of different species of microorganisms. Some interactions between species have been observed. The microflora exerts properties which are potentially damaging or health promoting for the host. A long established concept is that of beneficial and harmful species. Among components of the microflora, it has been suggested that bifidobacteria play a role in acting as a barrier against colonisation of the gastrointestinal tract by pathogenic bacteria. In addition to bifidobacteria, lactobacilli in particular have been examined concerning their role in the “barrier effect” against pathogens. Recent reports have documented that lactobacilli, a minor genus of the gut microflora, inhibit attachment of pathogens onto cultured uroepithelial and intestinal cells, and mucus. Moreover, reports have appeared showing that lactobacilli in gnotobiotic mice and continuous flow cultures can compete with *Escherichia coli* in the stomach and small intestine, whereas Clostridia have been found to control *E. coli* in the large intestine. Lactobacilli monoassociated mice and conventional mice treated with lactobacilli are protected against infection. Others reports show a potential for bifidobacteria, isolated from human adult stools, in inhibiting binding of pathogens in an in vitro model.

Our results presented here indicate that: (i) not all bifidobacterium strains resident in the infant microflora have antibacterial activity; (ii) the two infant bifidobacterium strains CA1 and F9 that developed antibacterial activity in vitro can colonise the digestive tract of germ free mice; (iii) the established infant CA1 and F9 bacteria exert efficient antimicrobial activity against *S. typhimurium* infection in mice. The relative area under the curve showed a large increase in CA1 and F9 monoassociated C5 infected mice (107 and 147, respectively) compared with germ free C5 infected mice (31).

To examine the levels of bifidobacteria colonising the intestine of mice, germ free C3H/He/Oujco mice received human infant bifidobacteria as a single dose. Seven days after administration, bifidobacteria were established in the intestine (table 5). A population of 4–6 log cfu/g of content was observed in the stomach and three parts of the small intestine for infant CA1 and F9 strains. A similarly high number of populations (9 log cfu/g of content) was found in the caecum and colon for the two infant strains. The level of bifidobacteria associated with the tissue was determined after the tissues were washed eight times with sterilised PBS. A population of 3–5 log cfu/g of tissue was observed in tissues of the stomach and three parts of the small intestine for infant CA1 and F9 strains. An identical population of 6–7 log cfu/g of tissue was found in the caecum and colon for the two infant strains.
mechanism by which bifidobacteria develop antimicrobial properties remains to be elucidated. Several reports have indicated that bifidobacteria could stimulate the immune system. For example, bifidobacterium strains increase the resistance of rats to salmonella infection. B breve YIT4064 enhances antigen specific IgA antibody directed against rotavirus in the mouse mammary gland protecting pups that receive milk against rotavirus challenge. Another report showed that a colonisation resistance mechanism against S typhimurium in human faecal bacteria associated mice inoculated with a mixture of bacteria isolated from the faeces of human breast fed infants containing B bifidum was related to lowering of the pH level and the presence of short chain fatty acids in the caecal contents. Another mechanism of action has been proposed as a B infantis strain developed broad spectrum antimicrobial properties through production of antimicrobial compounds, unrelated to acid production, which inhibited the growth of pathogens. We have recently provided evidence that selected bifidobacterium strains isolated from adult human stools inhibit binding of human enteropathogens to cultured enterocyte-like Caco-2 cells. Our results presented here and related to the antimicrobial activity of infant bifidobacterium strains are consistent with one of the mechanisms of action dependent on the production of antimicrobial compounds, as previously hypothesised. Indeed, we have provided evidence that the activity of the strains CA1 and F9 in vitro results from antimicrobial compounds present in the spent culture supernatants, suggesting that they are secreted. Interestingly, Fujiwara and colleagues recently described a proteinaceous factor(s) produced by Bifidobacterium longum SPB298, with a molecular weight of at least 100 000, which inhibited adherence of enterotoxic E coli strain Ptb16 expressing the colonisation factor adhesion II to the gangliotetrasylceramide GA1 molecule in vitro. We found that CA1 and F9 bifidobacteria produced an antibacterial lipophilic factor(s) with a molecular weight estimated as lower than 3500. Ibrahim and Bezkorovainy reported that organic acids of bifidobacteria serve as anti-infectious agents. The characteristics of bifidobacteria antimicrobial factor(s) resemble those of the antibiotic factor(s) produced by several lactobacilli strains and in particular those isolated from human stools and secreting antimicrobial compounds such as Lactobacillus casei rhamnosus GG. L johnsonii LA1, and L acidophilus LB which inhibit S typhimurium infection both in vitro and in vivo.

Over the past 10 years, evidence has accumulated that there is a non-immune system of defence in the intestine. By continual release of antibiotic proteins such as defensins and cryptidins, and enzymes such as lysozyme and phospholipase A, antimicrobial activity, specialised cells of the intestinal epithelium may influence the extracellular environment and contribute to mucosal barrier function. In parallel with the host cell non-immune system of defence, bacteria of the resident gut microflora also produce antimicrobial substances. The results presented here demonstrate that some species of the human microflora such as bifidobacteria could participate in the host defence against potential pathogenic microorganisms by producing anti-microbial substances.

This work was supported by a research contract between the Institut National de la Santé et de la Recherche Médicale (INSERM) and the Université Paris XI, and Nestec (Lausanne, Switzerland). We thank M Metoui for his careful reading of the manuscript.

Bifidobacterium strains from resident infant human gastrointestinal microflora exert antimicrobial activity
