NOD2 (CARD15) mutations in Crohn’s disease are associated with diminished mucosal α-defensin expression

Background: Mutations in NOD2, a putative intracellular receptor for bacterial peptidoglycans, are associated with a subset of Crohn’s disease but the molecular mechanism linking this protein with the disease pathogenesis remains unclear. Human α-defensins (HD-5 and HD-6) are antibiotic effector molecules predominantly expressed in Paneth cells of the ileum. Paneth cells also express NOD2. To address the hypothesis that the function of NOD2 may affect expression of Paneth cell defensins, we compared their expression levels with respect to NOD2 mutations in Crohn’s disease.

Methods: Forty-five Crohn’s disease patients (24 with NOD2 mutations, 21 with wild-type NOD2) and 12 controls were studied. Real time reverse transcription-polymerase chain reaction was performed with mucosal mRNA for HD-5, HD-6, lysozyme, secretory phospholipase A2 (sPLA2), tumour necrosis factor α, interleukin 8, and human hypoxanthine phosphoribosyltransferase (housekeeping gene). Immunohistochemistry with anti-HD-5 and histological Paneth cell staining were performed in 10 patients with NOD2 mutations or wild-type genotypes.

Results: Ideal expression of HD-5 and HD-6, but not sPLA2, or lysozyme, were diminished in affected ileum, and the decrease was significantly more pronounced in patients with NOD2 mutations. In the colon, HD-5, HD-6, and sPLA2 were increased during inflammation in wild-type but not in NOD2 mutated patients. In both the colon and ileum, proinflammatory cytokines and lysozyme were unaffected by NOD2 status. Immunohistochemistry identified Paneth cells as the sole source of HD-5.

Conclusion: As α-defensins are important in the mucosal antibacterial barrier, their diminished expression may explain, in part, the bacterial induced mucosal inflammation and ileal involvement of Crohn’s disease, especially in the case of NOD2 mutations.

Although the aetiology of Crohn’s disease is still enigmatic, the recent finding of a loss of function mutation in the putative intracellular peptidoglycan receptor NOD2 in approximately one third of Crohn’s disease patients represents a major advance.1–3 The pathophysiology of NOD2 in Crohn’s disease was initially proposed as being linked to immunological dysregulation in monocytes.4–5 However, intestinal epithelial cells,6 including Paneth cells,7 have also been demonstrated to express this putative receptor. It has been demonstrated that colonic epithelial cells with NOD2 mutations display a disturbed response against salmonella, supporting the hypothesis of a deficient antimicrobial response of epithelial cells.8 Nevertheless, the molecular mechanisms leading to diminished antibacterial responses in intestinal mucosal cells carrying functionally defective mutations of the NOD2 gene are not understood.

It is well known that epithelia are equipped with various antimicrobial peptides that act rapidly to kill a broad range of microorganisms.9 One important class of antimicrobial peptides are defensins. Defensins are small cationic arginine-rich peptides with a molecular weight of 3–5 kDa.10–11 Based on the position of three intramolecular disulphide bridges between cysteine residues, defensins are classified as α- and β-defensins. The known α-defensins include the human neutrophil peptides 1–4 as well as the epithelial human defensin 5 (HD-5) and human defensin 6 (HD-6). The α-defensins have a broad spectrum of antimicrobial activity against bacteria, fungi, and some enveloped viruses by perforating the cell membrane through formation of multimeric pores.12–14 They may also act as chemokines.15 HD-5 and HD-6 are Paneth cell products and major antimicrobial peptides of the small intestine.16 Expression of both HD-5 and HD-6 are increased in the colonic mucosa of inflammatory bowel disease patients through the appearance of metaplastic Paneth cells.17–19 Their functional importance is illustrated by the protection against salmonella in HD-5 transgenic mice20 and also by the increased susceptibility towards infection of matrilysin knockout mice, a protease which is responsible for the processing of murine prodefensins to defensins.21 Several investigations indicate that defensins are differentially expressed in Crohn’s disease and ulcerative colitis.21–23 Based on these data, as well as the recent finding of NOD2 expression in Paneth cells,5 we hypothesised that NOD2 may in part regulate or influence Paneth cell defensin expression. Another possible hypothesis is that NOD2 mutations could affect the number of Paneth cells. We reasoned that decreased expression of antimicrobial peptides may in principle lead to susceptibility to bacterial invasion which could trigger inflammation and loss of tolerance against the luminal flora. Furthermore, decreased Paneth cell defensin expression could potentially explain the ileal preference of Crohn’s disease patients with positive NOD2 mutations.24–26 To address these issues, we compared mucosal levels of human α-defensins in Crohn’s disease patients with respect to NOD2 (CARD15) genotypes.

Abbreviations: HD-5, human defensin 5; HD-6, human defensin 6; TNF-α, tumour necrosis factor α; HPRT, human hypoxanthine phosphoribosyltransferase; RT-PCR, reverse transcription-polymerase chain reaction; sPLA2, secretory phospholipase A2; IL-8, interleukin 8.
Ethics committee.

Frozen biopsies were available from 26 of 68 patients with Crohn’s disease which were stratified into those with \( \text{n} = 18 \) and without \( \text{n} = 8 \) macroscopic ileal disease. Colonic biopsies were available from 39 of 68 patients. In the case of Crohn’s disease, samples were taken from macroscopically inflamed and not inflamed mucosa, if possible. The diagnosis was based on standard criteria using radiological and endoscopic findings in every case. Patients were treated mainly with aminosalicylates, corticosteroids, or azathioprine according to their clinical requirements without any systematic differences between patients with NOD2 mutated or wild-type genotypes. Patient characteristics are shown in Table 1. All patients gave written informed consent before colonoscopy was performed. Samples were immediately snap frozen in liquid nitrogen. The study was approved by the local ethics committee.

Ribonucleic acid preparation and reverse transcription

Frozen biopsies were disrupted mechanically and total RNA was isolated using TRizol reagent (Invitrogen, San Diego, California, USA) according to the supplier’s protocol. RNA quality and quantity were determined by gel electrophoresis and photometry. Subsequently, 1 \( \mu \)g of total RNA was reverse transcribed with oligo dT primers and 200 U of Superscript (Invitrogen) according to routine procedures. These RNA preparations from each biopsy were used for assay of all defensins and cytokines tested.

Mutation analysis

Genotyping of genomic and/or cDNA for the functionally relevant NOD2 mutations (SNP8, SNP12, and SNP13) was performed using TaqMan technology (Applied Biosystems, Foster City, California, USA), as described previously. In brief, amplification reactions (25 \( \mu \)l) were carried out with 20 ng of template DNA, 1 \( \times \) TaqMan Universal Master Mix buffer (Applied Biosystems), 900 nM of each primer, and 200 nM of each fluorogenic probe. Detection of fluorescence signals was performed using the ABI PRISM 7700 detection system and the results were analysed as described previously by use of the Sequence Detection System (SDS) Software Version 1.7 (Applied Biosystems).

Real time polymerase chain reaction

We studied 24 patients displaying a NOD2 mutation, a demographically comparable Crohn’s disease group of 21 patients randomly selected from those with a NOD2 wild-type genotype, and 12 non-IBD patients without significant pathologic serving as controls. After isolation of mucosal RNA, real time reverse transcription-polymerase chain reaction (RT-PCR) was performed with specific primer pairs for HD-5, HD-6, lysozyme, secretory phospholipase A\(_2\) (sPLA\(_2\)), proinflammatory cytokines tumour necrosis factor \( \alpha \) (TNF-\( \alpha \)) and interleukin 8 (IL-8), as well as human hypoxanthine phosphoribosyltransferase (HPRT) as a control, in a fluorescence temperature cycler (LightCycler, Roche Diagnostics GMBH, Mannheim, Germany) and normalised to the amount of total RNA, as recommended and described previously.

This technique continuously monitors cycle by cycle accumulation of fluorescently labelled PCR product. Briefly, cDNA corresponding to 20 ng of RNA served as a template in a 20 \( \mu \)l reaction containing 4 mM MgCl\(_2\), 0.5 \( \mu \)M of each primer, and 1 \( \times \) LightCycler-FastStart DNA Master SYBR Green I mix (Roche Diagnostics). Samples were loaded into capillary tubes and incubated in the fluorescence thermocycler (LightCycler) for initial denaturation at 95\(^\circ\)C for 10 minutes followed by 45 cycles, each cycle consisting of 95\(^\circ\)C for 15 seconds, “touchdown” of \(-1\)\(^\circ\)/cycle from the primer specific start to end annealing temperature (Table 2) for five seconds, and 72\(^\circ\)C for 10 seconds. At the end of each

run melting curve profiles were produced by cooling the sample to 65°C for 15 seconds and then heating slowly at 0.20°C/s up to 95°C with continuous measurement of fluorescence to confirm amplification of specific transcripts. Cycle to cycle fluorescence emission readings were monitored and analysed using LightCycler Software (Roche Diagnostics). Lysozyme and sPLA2 control plasmids were used for standard curves. Lysozyme primers were used as described previously. Specificity of the amplification products was further verified by subjecting the amplification products to electrophoresis on a 2% agarose gel. Fragments were visualised by ethidium bromide staining and the specificity of PCR products was verified by sequencing of representative samples. Standard curves were obtained for each primer set with serial dilutions of DNA. Primer sequences and specific temperatures were used as shown in table 2.

**Immunohistochemistry**

Immunohistochemistry on colonic as well as ileal biopsies was performed with anti-HD-5 from 10 patients with Crohn’s disease (SNP8, 12, and 13 wild-type, n = 5; SNP13 heterozygotic, n = 4; SNP13 homozygotic, n = 1). The polyclonal anti-HD-5 was donated as a gift from T Ganz and E Porter (UCLA, USA) and immunohistochemistry was performed as described previously. 18

**Paneth cell staining**

In order to identify Paneth cells, we used phloxine tartrazine histological staining, as described previously. 16 HD-5
immunohistochemistry and histological staining were performed in parallel sections from all patients with available tissue.

Statistics

Mean expression values were obtained from duplicate or triplicate real time PCR measurements. Mean (SEM) values are presented. The U test of Wilcoxon, Mann-Whitney was used for statistical comparison of grouped data.

RESULTS

NOD2 mutation analyses

Fifteen of 68 patients were positive for SNP13 (12 heterozygotes and three homozygotes). Five were positive for SNP8 (four heterozygotes, one homozygote) and four patients displayed a mutation for SNP12 (heterozygotes only). Two of the 12 SNP13 heterozygote patients also displayed a SNP12 mutation. Three patients with a SNP13 mutation were also positive for SNP8 (compound heterozygote).

Gene expression of HD-5 and HD-6 was decreased in Crohn’s disease patients carrying a NOD2 mutation

Ileal expression

Of the Crohn’s disease patients with a NOD2 mutation, only one had a normal unaffected ileum. The group with ileal disease had diminished HD-5 expression compared with either controls or those with non-ileal Crohn’s disease (fig 1A). The level of expression was lowest in those with both the mutation and ileal disease. The expression pattern of HD6 was comparable (fig 1B) but did not attain statistical
significance. The group with ileal disease and NOD2 mutation had diminished HD-6 expression compared with either controls or those with non-ileal Crohn’s disease. One patient with a NOD2 mutation and a normal ileum displayed low HD-5 and HD-6 expression.

Compared with HD-5 and HD-6, expression of other Paneth cell products was not diminished by NOD2 mutations. Even though the difference failed to achieve statistical significance, lysozyme showed a tendency towards higher expression in NOD2 mutated patients (fig 1C). NOD2 mutated patients with ileal disease showed the highest levels of lysozyme (fig 1C). Ileal expression of sPLA2 was not influenced by NOD2 genotype. In common with HD-5 and HD-6, there was a tendency towards weaker expression in patients with ileal disease but this difference did not reach statistical significance (fig 1D).

Colonic expression

In non-inflamed colonic tissue, no difference was detected in expression of HD-5 or HD-6 in Crohn’s disease patients compared with controls. As expected, compared with ileal expression of Paneth cell defensins, expression levels in the colon were much lower. In samples with colonic inflammation, HD-5 was increased threefold in Crohn’s disease with the NOD2 wild-type genotype. However, Crohn’s disease patients with NOD2 mutations failed to show increased HD-5 or HD-6 expression in inflamed colonic tissue. In both HD-5 and HD-6, the difference between wild-type NOD2 genotype and SNP13 mutated patients was even more pronounced (insert in fig 2A, B).

Similar to observations in the ileum, lysozyme showed higher expression in the colon during inflammation (fig 2C). In comparison with control patients, expression of lysozyme was not altered in non-inflamed colonic tissue from Crohn’s disease patients. During inflammation, expression of lysozyme was higher but this increase was not statistically significant (fig 2C). The NOD2 genotype did not influence expression of lysozyme.

Similar to other products in non-inflamed colonic tissue, no difference was detected in expression of sPLA2 in Crohn’s disease patients compared with controls. In samples with colonic inflammation, sPLA2 was increased in Crohn’s disease with the wild-type NOD2 genotype (fig 2D). However, Crohn’s disease patients with NOD2 mutations failed to show increased sPLA2 expression in inflamed colonic tissue.

Ileal and colonic gene expression of TNF-α and IL-8 were not affected by NOD2 mutations

In contrast with HD-5 and HD-6, expression of the pro-inflammatory cytokines TNF-α and IL-8 were not significantly influenced by NOD2 genotype (fig 1E, 1F, 2E, 2F). A weak non-significant decrease in TNF-α and IL-8 gene expression in Crohn’s disease patients carrying a NOD2 mutation could be detected in ileal biopsies (fig 1E, 1F).

Normal number of ileal Paneth cells in patients carrying NOD2 mutations

Staining with phloxine tartrazine revealed a normal number of Paneth cells in ileal biopsies from four wild-type patients compared with three patients with a NOD2 mutation. Staining for a control and the SNP13 homozygote is shown in fig 3. A heterozygote patient exhibited metaplastic Paneth cells in the colon, similar in number to five NOD2 wild-type patients. However, the number of colonic biopsies with Paneth cell staining was too limited for a quantitative evaluation. Essentially, although with the same limitations,
the number of HD-5 positive cells was comparable between the groups. In parallel sections, Paneth cells also stained positive for HD-5, even in the homozygous patient, but the technique excludes quantitation of staining intensity (fig 3).

**DISCUSSION**

Crohn’s disease is a complex multifactorial disease whose pathogenesis is still not well understood. Recent research has focused on the role of luminal bacteria and their essential role in pathophysiology. A major advance for better understanding the disease is the discovery of mutations in the NOD2 gene in approximately one third of Crohn’s disease patients. NOD2 is a putative receptor of bacterial peptidoglycan which is also expressed by Paneth cells and crypt epithelial cells. Paneth cells are secretory cells expressing α-defensins HD-5 and HD-6. These antibiotic peptides are predominantly expressed in the small intestine and by metaplastic Paneth cells during inflammation in the colon. The findings reported herein for the first time link a mutation in NOD2 to reduced α-defensin expression in Crohn’s disease.

Mutations in the NOD2 gene are associated with ileal involvement in Crohn’s disease. As NOD2 and α-defensins are coexpressed in ileal Paneth cells, their relative deficiency in Crohn’s disease may be related to ileal preference, especially in patients with NOD2 mutations. Although the deficit in ileal α-defensins is particularly pronounced in NOD2 mutated patients, HD-5 is also reduced in NOD2 wild-type patients with ileal disease. This is compatible with the concept that other signalling peptides may be affected in NOD2 wild-type patients. Diminished expression of α-defensins, especially in patients with the NOD2 mutation, contrasts with the comparably enhanced levels of ileal mucosal TNF and IL-8 in both the NOD2 wild-type and mutated group with ileal involvement. Previous studies showed that Paneth cell populations as well as the secretory granule area are preserved or even increased in ileal Crohn’s disease, suggesting that Paneth cell function rather than number may be compromised in this disease. In the colonic mucosa, expression of HD-5 and HD-6 also seem to be regulated or influenced by NOD2 because lack of function mutations, especially SNP13, lead to diminished induction during inflammation. In contrast with diminished HD-5 and HD6 levels in the ileum of patients with a NOD2 genotype, enhanced levels of lysozyme and unchanged levels of sPLA2 in these samples suggest a selective influence on HD-5 and HD-6 expression by NOD2. However, in the colon, the observation that sPLA2 levels are influenced by NOD2 status is compatible with a role for this receptor in Paneth cell function or number. Possibly, the higher levels of lysozyme are produced by inflammatory cells in this tissue and unaffected by NOD2 mutation status.

Thus stratification of the Crohn’s disease cohort according to NOD2 status confirms the induction of α-defensins reported previously, and induction of sPLA2 only for those with intact NOD2 (that is, the majority of the patients).

In vitro data identify NOD2 as a putative intracellular peptidoglycan receptor molecule. We now suggest that it may be involved in the signalling cascade mediating α-defensin expression. In both cases, the defensin deficiency secondary to NOD2 mutations could lead to a breakdown of the mucosal barrier with a secondary inflammation. Recently, it has become apparent that the mucosal immune response in inflammatory bowel disease appears to be directed towards a multitude of common luminal bacteria. The most convincing evidence for a break in mucosal tolerance in intestinal inflammation stems from the observation that knockout mice lacking several relevant genes, including interleukins 2 or 10, develop experimental colitis only when raised in conventional housing, but not under germ free conditions. This fits well with the consistent finding of a break in mucosal tolerance towards various luminal bacteria in inflammatory bowel diseases. The permeable mucosal barrier may also explain the development of anti-Saccharomyces cerevisiae antibodies, especially in familial Crohn’s disease, as well as the presence of pathogenic bacteria. A more relevant finding in this regard is the presence of adherent Escherichia coli in the terminal ileum of Crohn’s disease patients. Similarly, Swidsinski et al demonstrated that the diseased epithelium may display attaching and even invading bacteria whereas normal mucosa handled under the same conditions is virtually sterile. These findings are difficult to reconcile with an immunological dysregulation as the sole basis of intestinal inflammation in these diseases. Rather, there may be a primary defect in the chemical defensin barrier, possibly involving other intestinal antimicrobial peptides which protect the normal mucosa extremely efficiently against adherent or entering microbes. It is also possible that a change in expression or function of this chemical defence may in part explain the changes in bacterial flora in inflammatory bowel diseases, as reviewed by Linksens and colleagues.

As some specific bacteria may downregulate defensin expression, it cannot be definitely excluded that diminished defensins may be due to a specific bacterial flora associated with Crohn’s disease. However, this possibility would be less attractive to reconcile the difference between NOD2 mutation and wild-type Crohn’s disease patients. The observation that HD-5 and HD-6 are unchanged during pouchitis (Kiehne et al abstract DDW 2002, Fellermann et al submitted for publication) strongly argues against speculation that downregulation of HD-5 and HD-6 accompanies inflammation alone. Although the functional relevance of defensins has been shown in mice, it still has to be proven in Crohn’s disease. The fact that ileal and colonic expression of proinflammatory cytokines are not influenced by NOD2 mutations further supports the specificity of the partial lack of certain defensins. Therefore, these data support the hypothesis that Crohn’s disease may be a complex defensin deficiency syndrome.

**ACKNOWLEDGEMENTS**

This work was supported by the Robert Bosch Foundation, Stuttgart, Germany. We thank Dr N Homann for data collection as well as Drs T Ganz and E Porter for supplying human defensin-5 antibody. We also thank P Miller, K Siegel, D Weller, D Biegger, as well as R Feathers for excellent technical assistance.

EDITOR’S QUIZ: GI SNAPSHOT

Answer
From question on page 1651
The patient was admitted for stent exchange after seven months (he missed the three month appointment). He was doing well, except for occasional burning right abdominal pain, with a net weight gain of 9 kg. There were no abnormal laboratory findings. On endoscopic retrograde cholangiography, no stents were detected and no remaining sticture of the bile duct could be seen. Repeated biopsies showed only regular bile duct epithelium. Abdominal ultrasound revealed a contracted gall bladder with persistent wall thickening and absence of cholestasis. [18F]Fluoro-2-deoxy-D-glucose-positron emission tomography (FDG-PET) showed marked remission with only minimal residual local activity enhancement (fig 1E). The case was reviewed, and retrospectively, chronic cholecystitis with subsequent pericholecystitis, due to Mirizzi syndrome, was considered the most likely diagnosis. The patient was considered eligible for cholecystectomy but refused surgery. Two years after the first admission the patient is doing well without signs of a malignant disease. Despite all modern imaging techniques, Mirizzi syndrome can still be a clinical chameleon.
