HCCR-1 for detecting small hepatocellular carcinoma latent in a cirrhotic liver: a prospective cohort study

We read with great interest the leading article by Tremosini and coworkers in Gut (2012 doi:10.1136/gutjnl-2011-301951) on the prospective validation of an immunohistochemical panel (glypican 3, heat shock protein 70 and glutamine synthetase) in liver biopsies for diagnosis of very early hepatocellular carcinoma (HCC).1 In this prospective study which included nodules <2 cm, this panel had 60% sensitivity and 100% specificity when at least two of the markers (regardless of which) were positive. These data establish the clinical usefulness of this panel of genetic biomarkers for the histological diagnosis of early HCC. The distinction between early HCC changes and dysplastic nodules among cirrhotic patients is challenging even in expert hands. Therefore, further prospective studies with a predominant inclusion of HCC lesions of <2 cm in diameter are needed for the final validation and confirmation of the conclusions of this interesting study.

Screening programmes have been developed for the surveillance of patients at risk of HCC (mainly liver cirrhosis) for detection at an early stage.2 Regrettably, a large proportion of small HCC does not meet the non-invasive diagnosis criteria (US, CT or MRI), and a biopsy should be requested for confirmation of HCC.2 Although a biopsy is usually considered the gold standard, it is also flawed by an excessive rate of false negative results.1

Despite the large number of studies devoted to the immunohistochemistry of HCC, the absolute positive and negative markers for HCC are still lacking, and even those characterised by very high sensitivity and specificity do not have a universal diagnostic usefulness. So far, serum biomarkers such as AFP, AFP-L3, DCP, AFU, GGT, GP-73, MUC-1, SCCA, GPC-3, and a new generation of IgM-immunocomplexes have significant diagnostic limitations, and in fact they are not particularly precise for the early diagnosis of HCC. Simultaneous determination of three biomarkers yielded an improved sensitivity of 75.4% for detecting HCC. When only those with early HCC were evaluated, the AUC for AFP and HCCR-1 was almost identical, while that of DCP was rather low (figure 1). In addition, the sensitivities of AFP, DCP and HCCR-1 in small HCC (<2 cm) were 39.7%, 15.5% and 51.9%, respectively, using the currently recommended cut-offs for AFP (20 ng/ml), DCP (40 mAU/ml) and HCCR-1 (10 ng/ml) (data not shown). The one-year cumulative incidence rates of HCC for cirrhosis patients positive for AFP or HCCR-1 were 15.0% and 20.4%, respectively. HCCR-1 was also

Figure 1 ROC curves comparing AFP, DCP and HCCR-1 in patients with HCC (Panel A) or small HCC (Panel B) versus those with non-malignant liver disease. The curves show the optimal cut-off value for AFP of 10 ng/ml, for DCP of 22 mAU/ml, and for HCCR-1 of 1.96 ng/ml. The area under the ROC curve is shown with its 95% confidence interval (table 1). A combination of three biomarkers yielded an improved sensitivity of 75.4% for detecting HCC. When only those with early HCC were evaluated, the AUC for AFP and HCCR-1 was almost identical, while that of DCP was rather low (figure 1). In addition, the sensitivities of AFP, DCP and HCCR-1 in small HCC (<2 cm) were 39.7%, 15.5% and 51.9%, respectively, using the currently recommended cut-offs for AFP (20 ng/ml), DCP (40 mAU/ml) and HCCR-1 (10 ng/ml) (data not shown). The one-year cumulative incidence rates of HCC for cirrhosis patients positive for AFP or HCCR-1 were 15.0% and 20.4%, respectively. HCCR-1 was also
detected in 35.9% (52/145) of HCC-negative both for AFP and DCP. Therefore, our study suggests that the HCCR-1 could be a useful biomarker for the detection of small HCC (<2 cm), for the detection of HCC latent in a cirrhotic liver, and for the diagnosis of both AFP- and DCP-negative HCC.

Acknowledgements We are grateful to the patients who participated in this project. PJ, GZ, S-AH and HKK equally contributed to this manuscript.
