Biliary excretion of enterokinase in rats: studies in alcoholic rats with fatty liver

D A W GRANT, T R TERRY, and J HERMON-TAYLOR

From the Department of Surgery, St George's Hospital Medical School, London

SUMMARY Ethanol-associated fatty liver was induced in rats fed a nutritionally deficient liquid diet containing 36% of total calories as ethanol. Control rats received the same diet with sucrose substituted isocalorically for ethanol. After 40 days, hepatic lipid content of the ethanol-maintained animals was four-fold greater than controls and ultrastructural changes in hepatocytes were well established. Clearance of intravenously administered human enterokinase from the circulation as well as bile flow were, however, the same in both groups. The proportion of enterokinase appearing in catalytically active form in bile after intravenous injection was substantially greater in the ethanol-maintained animals than the isocaloric controls; the difference was highly significant ($p < 0.001$) and reached two- to four-fold after 70 days on the diet. These findings would suggest that the ability of hepatocytes to degrade enterokinase cleared from the blood may be bypassed or impaired by prolonged ethanol consumption and a deficient diet. Catalytically active enterokinase in bile may participate in the development of some types of acute necrotising pancreatitis.

In an earlier study we proposed that a critical event in the aetiology of alcohol-induced acute necrotising pancreatitis may be the transfer into bile of small amounts of catalytically active enterokinase sequestered from the proximal small intestine into portal blood.¹ A crucial factor in this proposal was the demonstration that intravenously administered enterokinase was excreted in catalytically active form in the bile of both normal rats and rats that had been drinking 20% (v/v) ethanol for one year. The kinetics of enterokinase excretion were similar to those described for other serum-derived proteins.² The proportion of intravenously administered enterokinase secreted in bile was 1-2% in both normal and ethanol-maintained rats when up to six successive doses of enzyme were given at 90 minute intervals. When the enzyme was injected every 30 minutes the proportion of administered enterokinase appearing in bile of ethanol-maintained rats was higher than in weight-matched normal controls. The difference was, however, not great, probably because 20% ethanol with a nutritionally adequate solid diet did not produce sufficiently marked changes in liver function.

The present study describes the clearance from

blood and subsequent biliary excretion of intravenously administered human enterokinase in rats which progressively developed fatty livers and other evidence of hepatocyte damage by being maintained on a nutritionally inadequate liquid diet in which 36% of total calories were provided by ethanol.³ Animals receiving this diet were compared at intervals with weight-matched pair-fed control animals which received an identical diet, except that sucrose was isocalorically substituted for ethanol.

Methods

DIET

The vitamin, mineral, fat, and amino-acid constituents of the diet described by Lieber *et al*³ were supplied ready-mixed by BP Nutrition (UK) Ltd, Witham, Essex CM8 3AB. Vitamin and fat-free casein was used as the protein source, as its amino-acid composition was comparable with the published diet. A nutritionally depleted diet sufficient to maintain body weight but not growth was made up by liquidising 45 g of the solid constituents in 500 ml warm tap-water. This was added to 436 ml water containing 100 g sucrose and the mixture was made up to 1 litre by the addition of 64 ml ethanol (equivalent to 50 g/l). The diet

contained approximately 22% of total calories as fat and protein, 42% as sucrose, and 36% as ethanol. The control diet had sucrose isocalorically substituted for ethanol by adding 190 g of the sugar per litre of diet.

Individually caged female Wistar rats weighing between 175–200 g were divided into two groups of 20. Rats drinking the ethanol-impregnated diet were introduced to the diet over a period of six days by progressively increasing the ethanol content to 50 g/l. Once established on this diet the other 20 rats were pair-fed the same amount of the control diet as their experimental counterparts had consumed on the previous day. Animals were weighed every five days; two rats in the experimental group were removed from the study because of failure to accept the diet.

ENTEROKINASE

Human enterokinase was purified to homogeneity as previously described.⁴ The enzyme was assayed in rat serum and bile using the synthetic substrate glycyl-L-tetra-aspartyl-L-lysyl- β -naphthylamide at a final Zn^{2+} concentration of 2.5 mM.⁵

ANIMAL STUDIES

Four rats from each group were tested on days 10, 20, 40, and 70 for their ability to clear intravenously administered enterokinase from the circulation and subsequently to excrete it into bile. The bile duct and femoral vein were cannulated as previously described.¹ One rat in each group of four received three intravenous doses at 90 minute intervals of 15 μg human enterokinase in 0.5 ml saline; 0.3 ml systemic blood samples were collected at one, two, five, 10, and 20 minutes after administration of the first and last dose. Hepatic bile was collected as 15 minute samples over the 4.5 hour experimental period. In a similar experiment a second rat from each group of four received three doses of 7.5 μg enterokinase. The two remaining rats from each group received three intravenous doses at 30 minute intervals of either 7.5 μg or 15 μg human enterokinase; blood and bile samples were collected as described.

LIVER ANALYSIS

At the end of each experiment liver biopsies were taken from each rat and fixed in 10% formalin for histological examination. Additional material was finely minced and fixed in 3% ice-cold gluteraldehyde for electron microscopy. The remainder was divided into three weighed portions of 1–1.5 g each and stored in a chloroform:methanol:water mixture (85:14:1) at 4°C before estimation of total lipids by the method of Folch *et al.*⁶

STATISTICAL ANALYSIS

The significance of apparent differences in the proportion of intravenously administered human enterokinase secreted in bile of ethanol-maintained and control groups was tested using a four-way factorial analysis of variance.

Results

The lipid content of the livers (mg lipid/g tissue $\pm$ 1 SD) of the chronic ethanol-maintained and control rats respectively was 100 ± 26 and 66 ± 26 after 10 days, 107 ± 35 and 40 ± 6 after 20 days, 243 ± 31 and 61 ± 19 after 40 days, and 186 ± 57 and 41 ± 13 after 70 days on the nutritionally deficient diet, confirming the development of changes previously described by Lieber *et al.*^{7,8} Fat deposition in the livers of ethanol-maintained rats was gross on light microscopy, and ultrastructural changes in hepatocytes including fragmentation of rough endoplasmic reticulum, hyaline deposition, swelling of mitochondria, and damage to bile ductules was obvious by day 40. These ultrastructural changes were not seen in control animals. The volume of bile produced during the tests was apparently unaffected, the mean flow rate being 460 ± 70 $\mu\text{l/h}$ in ethanol-maintained rats, and 488 ± 104 $\mu\text{l/h}$ in controls. The half-life of enterokinase in the blood (<2.5 minutes) and the completion of enterokinase excretion in bile (<1 hour) was the same for the ethanol-maintained and control animals.

The proportion of the intravenously administered doses of human enterokinase secreted in the bile of chronic ethanol-maintained and control rats after 10, 20, 40, and 70 days on the nutritionally deficient diet is shown in the Table. The proportion of the enzyme appearing in the bile of ethanol-maintained animals was considerably greater than in the isocaloric control group; the difference was highly significant ($p < 0.001$, variance ratio (F) 25.8) and by day 70, two to four times as much enterokinase was found in the bile of the ethanolic rats compared with their pair-fed controls.

Discussion

Human enterokinase is a large molecule with an apparent molecular weight of about 300 000.⁹ It is itself particularly resistant to proteolysis^{9,10} and is one of the most heavily glycosylated enzymes known.^{9,11} The enzyme might be expected to persist in the circulation for a considerable time. Previous studies have, however, shown that this is not the case, and that the half-life ($t_{1/2}$) of both the human and murine enzymes in the circulation of mice is about 2½ minutes;¹² a similar $t_{1/2}$ has been found in the

Table Mean percentage of three intravenous injections of human enterokinase secreted in bile of chronic ethanol-maintained and control rats fed a nutritionally deficient liquid diet*

Days on diet	Chronic ethanol-maintained rats				Isocaloric pair-fed control rats			
	Injection every 30 min of		Injection every 90 min of		Injection every 30 min of		Injection every 90 min of	
	7.5 µg	15 µg	7.5 µg	15 µg	7.5 µg	15 µg	7.5 µg	15 µg
10	1.9	1.8	2.0	1.8	0.64	0.96	1.8	1.3
20	1.3	1.9	1.9	1.5	ND	1.1	1.6	1.3
40	4.2	1.8	1.8	2.9	2.5	1.0	0.81	0.83
70	3.5	2.15	2.2	1.5	0.9	0.85	1.3	0.83

rat¹ and guinea-pig. Immunofluorescent studies have identified the enzyme in hepatocytes after intravenous administration.¹² As enterokinase persists in the circulation after periodate oxidation of its peripheral sugars,¹² it seemed likely that its rapid clearance from blood is dependent on specific recognition of its carbohydrate moiety by hepatocyte receptors in a manner similar in principle to that previously described for the elimination of asialoglycoproteins.¹³⁻¹⁵ In the presence of normal liver function a small proportion of circulating enzyme appears in bile in active form. Distortion of liver architecture in experimentally induced (CCl₄) cirrhosis prolongs the $t_{1/2}$ of enterokinase in the circulation and reduces biliary excretion.¹

The present study shows that, in the presence of unequivocal evidence of ethanol-associated liver damage in rats (and in the absence of cirrhosis), there is a substantial and significant rise in the amount of circulating enterokinase appearing in the bile in catalytically active form. Unlike the findings in cirrhotic animals,¹ clearance of the enzyme from the circulation appeared normal, and it seems reasonable to conclude that access to the sinusoidal surface of the hepatocytes and their ability to take up the enzyme from blood was unaffected. Involvement of Kupffer cells in the uptake of intact glycoprotein cannot, however, be excluded.² Bile flow and the time course of enterokinase excretion in bile appeared unchanged by the development of an ethanol-damaged fatty liver. The substantial increase in biliary excretion of active enterokinase in ethanol-maintained animals would suggest that the ability of their hepatocytes to degrade enterokinase may have been bypassed¹⁷ or impaired.¹⁸ If catalytically active enterokinase appears in human bile under pathophysiological conditions, it may, in appropriate circumstances, participate in the development of acute necrotising pancreatitis whose association with fatty liver is well described.^{19, 20} It is

interesting to note that alcohol-induced acute necrotising pancreatitis is more often associated clinically with reversible fatty liver than with cirrhosis.¹⁹

The authors gratefully acknowledge the help of Dr G Uff, Department of Histopathology, St George's Hospital Medical School, in the preparation of the histological sections and Dr J Foster, British Industrial Biological Research Association, for the processing of the electron micrographs. Statistical calculations were kindly performed by Dr Martin Bland, lecturer in statistics. Financial support was given by the St George's Hospital Medical Research Committee and the Wellcome Trust. Mr T R Terry held a Wellcome Trust surgical research fellowship.
