Evolution of hereditary non-polyposis colorectal cancer

J R Jass, S M Stewart

Abstract

The prevalence of colorectal adenoma in 23 affected patients with hereditary non-polyposis colorectal cancer (HNPCC) was compared with that in an age matched forensic autopsy population. The mean ages at diagnosis of colorectal cancer in men (13) and women (10) were 39 and 37 years respectively. In HNPCC patients who presented below the age of 50 years, at least one adenoma was found in 3 of 10 (30%) men and in 4 of 9 (44%) women. In the age matched autopsy specimens of large bowel, a solitary adenoma was found in 2/42 (5%) men ($p=0.015$) and 1/21 (5%) women ($p=0.0075$). Of the 11 adenomas from HNPCC patients, nine were greater than 1 cm and six showed a pure villous architecture. Contiguous adenocarcinoma was observed with six adenomas. Adenomas do not occur in large numbers in HNPCC, but develop at a young age, attain a large size, often show a villous configuration, and are more prone to malignant conversion than sporadic adenomas.

Evidence is accumulating that hereditary non-polyposis colorectal cancer (HNPCC) is a distinct clinicopathological entity.¹⁻⁶ Examination of family pedigrees points to an autosomal dominant pattern of inheritance, with the syndrome being distinguished from sporadic colorectal cancer by the young age of onset of malignancy. Cancers show a predilection for the right colon. It has been estimated that 5% of colorectal cancers arise through the inheritance of a dominantly acting gene,⁷ and it has been suggested that screening for

large bowel cancer should be targeted towards individuals with a family history suggestive of HNPCC.^{5,8} While this represents a relatively small high risk group, the potential loss of years of life is relatively great in view of the young age of onset of cancer. An important additional feature of the syndrome is the increased frequency of certain extracolorectal malignancies, notably of uterus, ovary, breast, stomach, and small intestine.^{9,10} Notwithstanding the body of data relating to HNPCC, there is little information available on the pathogenesis of cancer. It is important to establish the nature of precancerous lesions, if any, as this will have a bearing on the design of preventive strategies. This study aimed to compare the prevalence and histopathology of adenomas in affected members of HNPCC families with an autopsy population in an attempt to understand the role of adenoma in the evolution of HNPCC.

Patients and methods

For the purposes of this study, the minimum criteria defining a family with HNPCC were at least three relatives (one of these being a first degree relative of the other two) with colorectal cancer implicating at least two successive generations. Clinical and pathology details of affected families are held in a registry whose function has been approved by the Auckland Hospital Research Ethics Committee. Ascertainment of patients was through receiving reports of a strong family history of colorectal cancer. One of the families has been documented previously.¹¹

The study was based on 23 patients from four

families whose pathology records could be traced. Confirmation of histological findings was achieved in 22. Twenty one patients were from two families and all four families were of European descent. There were 13 men and 10 women. Nine have died as a result of their bowel cancer and the remainder are alive and well.

Adenomas occurred in the initial surgical specimen, in subsequent operative specimens, or were found on endoscopic examination of the remaining large bowel. Age at discovery of the first adenoma was taken to compare prevalence with the control group. In patients without adenomas, age stratification was based on the age on the occasion of the most recent negative report. The maximum diameter of the adenoma was obtained from the histological preparation and the lesions were typed as tubular, tubulovillous, and villous according to WHO criteria.¹² In addition, adenomas were graded as showing mild, moderate, or severe dysplasia. Adenocarcinomas were typed and graded according to WHO criteria¹² and the invading border was classified as expanding or infiltrating.¹³ Staging was by the method of Dukes.¹⁴

Colorectal specimens from 158 coronial autopsies served as a control group. The hepatic and splenic flexures were indicated with string ties and the rectum removed in continuity by dissecting down to the pelvic floor. The specimens were examined in the fresh state by the first author and all polyps were removed for histological examination. Locations of polyps were marked on a diagram. The large bowel was then returned to the body. Specimens from Maoris and Polynesians were excluded. Deaths were the result of accident, suicide, or sudden causes with no known association with bowel neoplasia. The polyps were measured after fixation and histological sections were prepared and stained with haematoxylin and eosin. Polyps were classified as

adenomas, hyperplastic polyps, unclassified, and other. The unclassified polyps were small nodules with severe autolysis. Adenomas were typed as tubular, tubulovillous, and villous¹² but autolysis made the grading of dysplasia subjective.

Results

Clinical and pathological details of the patients used in this study are summarised in Table I. For the purposes of this study, right colon comprised the caecum and transverse colon and left colon extended from the splenic flexure to the rectosigmoid junction. The distribution of adenocarcinoma (excluding the smaller synchronous and all metachronous malignancies) is shown in Table II.

The distribution of adenoma in the study group is compared with the autopsy group in Table III. The autopsy series yielded 105 adenomas. Most of these were tubular and there were no pure villous types. In the study group, 8 of 11 adenomas showed a villous component and six of these were pure villous tumours (Table IV). Nine adenomas showed moderate or severe dysplasia. In the autopsy series most adenomas were less than 10 mm in diameter whereas the opposite was true for the study group (Table V). There were six instances of unequivocal adenoma contiguous with infiltrating adenocarcinoma in the study group.

Patients were stratified into age groups of less than 50 years, 50 to 69 years, and older than 70 years in order to compare the prevalence of adenoma in the autopsy and study groups. In this study group most adenomas presented in individuals under the age of 50 years and it was in this subset that important differences from the autopsy group could be discerned (Tables VI and VII).

Discussion

Patients included in this study seem to belong to families with the characteristics described by Lynch.^{19,10} They were selected on the basis of a family history that would be consistent with an autosomal dominant tendency for the development of colorectal cancer. The mean age at diagnosis of cancer was low (39 years for men and 37 years for women). Other features described by Lynch were present. These included a predilection for the right colon (Table II), an increased incidence (22%) of multiple large bowel cancer,¹⁶ and features of a relatively low tumour aggressiveness. The latter included a low cancer related mortality (9/23 patients), relatively few Dukes's C cases (22%), and few tumours showing a diffuse pattern of infiltration (4%). The proportion of mucinous carcinomas was greater than expected (18%),¹³ supporting the findings of Mecklin *et al.*¹⁷ However, the proportion of carcinomas according to grade of differentiation was as expected.¹³ In keeping with kindreds described by Lynch,^{9,10} particular extracolonic malignancies occurred, including two endometrial carcinomas in patients with colorectal cancer as well as endometrial carcinomas (3), ovarian tumours (2), breast carcinoma (1), gastric

carcinoma (1), and small intestinal carcinoma (1) in other family members without colorectal cancer.

Relatively little is known of the role of adenoma in the evolution of cancer in HNPCC. Lynch has previously stressed the absence of promonitory lesions,² but recently concluded that adenomas are precursors of cancer in HNPCC.¹⁸ Although his study showed an excess of adenomas in family members, this was because 12 members of a single family had multiple adenomas, many of which were flat. Some of these families may represent variants of familial adenomatous polyposis.¹⁹ When this unusual family was excluded from the analysis, there was no difference in adenoma prevalence between the remaining Lynch syndrome patients and a control group.¹⁸ Other endoscopic screening studies of HNPCC families have reported a high detection rate for adenoma and carcinoma in at risk patients, but have lacked a control group.^{5,8} Screening aimed specifically at families showing the characteristics of HNPCC should be distinguished from surveys based solely on a positive family history.^{20–26} These studies will yield a relatively heterogeneous patient sample.

Further clarification of the evolution of bowel cancer has come from detailed pathology surveys. Lovett found that patients with a positive family history of bowel cancer had more adenomas in their surgically excised specimens than patients with a negative family history.²⁷ This survey did not deal specifically with HNPCC. A review of HNPCC families by Love showed the presence of malignant change within adenomas.²⁸ It was noted that adenomas occurred no more frequently in HNPCC subjects than in individuals with sporadic colorectal cancer, but developed at an earlier age. Mecklin *et al* confirmed the similar prevalence of adenomas in hereditary and sporadic cancer specimens, but noted a high incidence of adenomas with moderate or severe dysplasia and villous features within the hereditary group.¹⁷

The findings of the present study are similar to those of Love²⁸ and Mecklin *et al*.¹⁷ The data point to the relative rarity of adenomas in HNPCC, the tendency for adenomas to occur at

an early age, the origin of carcinoma within adenoma, and the high incidence of adenomas with a villous growth pattern and moderate or severe dysplasia. In addition, the HNPCC adenomas seem to have a greater potential for growth. These findings become more significant when one heeds the inherent biases that would reduce the differences between study and control groups. These include the retrospective nature of HNPCC data, the lack of information regarding the entire colon in some HNPCC patients, the complete or partial destruction of adenoma by carcinoma in HNPCC patients, and, with respect to pathological features of adenomas, the considerably older age of the autopsy population. The single bowel examination in the control group would not bias the data in favour of the HNPCC group if it is assumed that adenomas increase in size with time. In any event, of the eight adenomas occurring in patients under 50 years, seven were found at the time of the original operation.

It is surprising that six of the 10 adenomas occurred in the rectum given the low prevalence of carcinoma at this site, particularly in men. It is possible, however, that adenomas in the right colon existed previously but were destroyed by cancer. The low prevalence of left colonic adenomas matches the low figure for carcinoma in this site, particularly in women.

The HNPCC gene seems to predispose affected individuals to the development of small numbers of aggressive adenomas at a young age. The biological differences between sporadic and HNPCC adenomas are perhaps not as great as the differences between HNPCC adenomas and those occurring in familial adenomatous polyposis. In the latter, many thousands of adenomas develop, but are slow growing, are usually tubular, and, individually, have a low malignant conversion rate. In HNPCC, adenomas are relatively uncommon and individually must have a high malignant conversion rate. It is likely that the molecular events underlying the pathogenesis of adenoma differ considerably in the three clinical scenarios of sporadic colorectal cancer, HNPCC, and familial adenomatous polyposis.²⁹ These differences could be in the mutations themselves or as a result of a different order of mutational steps. The inherited gene in HNPCC may be a critical and rate limiting step and its constitutional presence would thus accelerate the evolution of adenoma. It is likely to be a tumour suppressor gene that would produce no effect until the homologous gene had been lost through a mechanism such as mitotic non-disjunction.³⁰ This would account for the focal nature of neoplastic change in HNPCC.

The above suggestions are speculative but fit well with the pathological observations described. The findings support the need for adenoma surveillance in HNPCC but point to the possibility of rapid evolution which would necessitate short interval screening in this group of patients.

This study was supported through grants from the Cancer Society of New Zealand and the Auckland Medical Research Foundation. The data could not have been collected without the help of clinicians and pathologists in New Zealand, Australia, and Great Britain, to whom we express our gratitude.
