Prevalence of *Helicobacter pylori* in patients with gall stones before and after cholecystectomy: a longitudinal study

N A Abu Farsakh, E Roweily, M Steitieh, R Butchoun, B Khalil

Abstract

Fifty six patients with gall stones were enrolled in this study to assess the presence of *Helicobacter pylori* in gastric mucosa before and after cholecystectomy. Samples were taken from gastric juice and antral mucosa through endoscopy performed on these patients before and after the operation. Gastric juice was examined for bile salt concentration as an indicator of duodenogastric reflux. Antral mucosa was studied for the presence of *H pylori* and inflammatory response. Duodenogastric reflux was significantly increased ($p < 0.001$) and *H pylori* significantly decreased ($p < 0.01$) in the postoperative period. Mucosal inflammation and its activity were less in the postoperative period but the differences did not reach statistically significant values.

(Gut 1995; 36: 675-678)

Keywords: *Helicobacter pylori*, cholecystectomy, gall stones.

Since its culture by Marshall *et al* in 1982,¹ *Helicobacter pylori* has been found in gastric biopsy specimens and linked to many diseases in the gastrointestinal tract. It has been isolated from patients with duodenal ulcers in 80-100%, from type B gastritis in 70-90%, in gastric ulcers 58-86%, in atrophic gastritis 43-89%, in non-ulcer dyspepsia in 43-87%, and in patients with gastric carcinoma in 19-80%.²⁻¹⁰ After gastric operations prevalence of *H pylori* ranged from 26-40%. This decreased frequency after gastric operations was attributed to increased concentration of bile salts in gastric juice resulting from increased duodenogastric reflux in these patients.^{11 12} In asymptomatic normal populations, rates of isolation of *H pylori* were between 13-87%, increasing in frequency with advancing age.¹³⁻¹⁷ In Jordanians, studies showed a prevalence of 70% in patients with acute gastritis, 73% in chronic gastritis, and 83% in patients with duodenal ulcers.¹⁸

Patients with gall stones may be asymptomatic or may complain of biliary colic. Presence of various dyspeptic manifestations in patients with gall stones was found to be similar to their prevalence in the general population^{19 20} although few studies suggest an association between both disorders.^{21 22} Relief of these dyspeptic manifestations occasionally occur after cholecystectomy while others may show persistence of their symptoms or even

may develop dyspepsia after cholecystectomy; the postcholecystectomy syndrome.^{23 24} Is there a link between *H pylori* and gall stone disease? To our knowledge prevalence of *H pylori* has not been assessed in patients with gall stones or in postcholecystectomy patients and its relation to dyspepsia in this group of patients has not been studied. In this study we tried to assess prevalence of *H pylori* in these patients, which may be important for the better understanding of dyspeptic manifestations in this group.

Methods

Patient group

Fifty six patients (48 women and eight men), who were diagnosed to have gall stones by ultrasonography at Princess Basma Teaching Hospital in Irbid, northern Jordan, were included in this study. Age range was 22-70 years with a median age of 44. Patients who were included had no previous gastric surgery and no history of serious medical illness. They were evaluated before the operation and 3-30 months postoperatively by gastroscopy, biopsy, and bile salt determination in gastric juice.

Gastroscopy and biopsies

Upper gastrointestinal endoscopy was performed after an overnight fast. Antral mucosal biopsy specimens were taken using sterilised biopsy forceps. Specimens were always taken from an area of intact mucosa within 5 cm from the pylorus and sent for histopathological and microbiological examination.

Histopathological examination

Three to five samples were fixed in 10% formalin, embedded in paraffin wax, and stained with haematoxylin and eosin. *H pylori* was identified by morphology and labelled as either present or absent accordingly. Antral mucosa was assessed for the presence of inflammation, which was reported to be present if inflammatory cells were seen in the mucosa. The inflammation was assessed to be acute when polymorphs were seen in the lamina propria or intraepithelially, or both.^{3 25-27}

Microbiological examination

One to two samples were aseptically transported into a sterile pijo bottle containing

TABLE I Results of *H pylori* isolation, presence of inflammation, and gastric bile salt concentration in 56 patients with gall stones before operation

Inflammation	Bile				Total
	H pylori present		H pylori absent		
	>1 mmol/l	<1 mmol/l	>1 mmol/l	<1 mmol/l	
No inflammatory response	0	2	2	3	7
Chronic inflammation	4	15	2	3	18
Acute on chronic inflammation	10	28	2	3	31
Total	14	45	6	11	56

5 ml of sterile brain heart infusion broth (Difco Lab, Detroit, USA), cultured on blood agar plates (Difco), and incubated at 37°C under microaerophilic conditions for 7–14 days. Developing colonies were identified as *H pylori* based on colonic morphology, Gram stain, production of catalase, oxidase, and urease.²⁸

Bile salt determination

Five ml of fasting gastric juice were taken during endoscopy for determination of bile salts using thin layer chromatography and a purified 3 α hydroxysteriod dehydrogenase.²⁹

Statistical analysis

McNemar's test was used for statistical analysis of dependent data.

Results

Bacteriological and histological evaluation to study *H pylori* before and after operation (112 samples) was carried out in these 56 patients as described. In 102 samples, both results were identical, a concordance rate of 91%. Results in 10 samples were discordant, three were negative by histopathology and seven were negative by bacteriological examination. All discordant results were considered positive.

Before operation, 45 of 56 patients were positive for *H pylori* (80%), while in 11 patients *H pylori* was not identified (20%). After cholecystectomy, nine further patients were cleared of *H pylori*, increasing the total number who were negative for *H pylori* to 20 of 56 patients (36%) ($p < 0.01$).

Inflammation was seen in the antral mucosa in 49 patients (88% of total) before the operation, 43 of them were *H pylori* positive. Inflammation was reported to be acute in 31

patients (55% of total), 28 were *H pylori* positive. After cholecystectomy, 46 patients showed inflammation, 24 of 46 (43%) showed acute inflammation, these results were not statistically significant ($p > 0.05$).

Bile salt concentration in the fasting gastric juice was reported to be higher than 1 mmol/l in 20 patients before operation (36%), while after cholecystectomy, 28 more patients showed increase in their bile concentration to more than 1 mmol/l, raising the total number with high bile concentration to 48 patients (86% of total). This result is highly significant ($p < 0.001$). Of these 28 patients who showed a rise in their bile concentration, nine patients were positive for *H pylori* before operation but cleared the bacteria after operation (32%).

Tables I and II show details of the findings before and after operation.

Discussion

H pylori has been clearly shown in many studies to be associated aetiologically to chronic type B histological antral gastritis, characterised by polymorphs and mononuclear cells infiltrating the superficial epithelium and the lamina propria.^{25–30} Bile salts were shown to cause a different type of gastritis, the enterogastric reflux gastropathy; which is characterised histologically by paucity of inflammatory cells in the lamina propria. This type of gastritis was reported in most patients after vagotomy or gastrojejunostomy. Prevalence of *H pylori* was much lower in this alkaline reflux compared with its high prevalence in type B antral gastritis.^{21–32} Reflux of bile was reported to decrease the recovery of *H pylori* from gastric specimens. Although in vitro studies have suggested an inhibitory effect for bile salts on *H pylori* growth, their exact role in vivo needs to be evaluated further.^{33–34}

In our study, it was clearly shown that duodenogastric reflux was considerably increased in postcholecystectomy patients compared with their preoperative status: 36% in preoperative patients compared with 86% postoperatively as evidenced by increased bile salt concentration above 1 mmol/l ($p < 0.001$). *H pylori* was identified either histologically or microbiologically in 45 of 56 (80%) in patients with gall stones. Postoperatively, *H pylori* was identified in 36 of 56 patients (64%). This decrease, which is statistically significant ($p < 0.01$), can be explained by the higher concentration of bile salts or other unrecognised factor(s) present in or caused by the refluxed juice, affecting colonisation of *H pylori* in the gastric epithelium.

The decrease in *H pylori* colonisation in the gastric mucosa was reflected histologically by decrease in the components of acute inflammation as evidenced by polymorph infiltration in the lamina propria or intraepithelium, or both, which was present in 29 patients preoperatively versus 20 in the postoperative period. Total number of patients who showed inflammatory response also dropped from 32 preoperatively to 24 patients in the postoperative period but this difference did not reach statistically

TABLE II Results of *H pylori* isolation, presence of inflammation, and gastric bile salt concentration in 56 patients with gall stones after operation

	Bile				
	H pylori present		H pylori absent		
Inflammation	>1 mmol/l	<1 mmol/l	>1 mmol/l	<1 mmol/l	Total
No inflammatory response	0	0	8	2	10
Chronic inflammation	16	0	6	0	22
Acute on chronic inflammation	16	4	2	2	24
Total	32	4	16	4	56

significant values. Patients who had *H pylori* without inflammatory response in gastric mucosa cleared the bacteria postoperatively. These results showed that colonisation of *H pylori* in gastric epithelium is directly related to the activity of inflammation in the antral mucosa, and both were inversely related to the concentration of bile salts in gastric juice.

Although the relation between gall stones and dyspeptic manifestations is mostly an association of two common disorders, evidence exists in published reports that suggests that some patients with dyspepsia and gall stones are affected favourably after cholecystectomy,^{22 35} while others show persistence of their symptoms or develop new symptoms after the operation. The last two groups are considered part of what is labelled as the post-cholecystectomy syndrome.^{23 24}

Is the increase in duodenogastric reflux and the change in bile acid concentration in gastric juice with the consequent fall in *H pylori* colonisation related to this change in dyspepsia? To answer this question, several points should be considered. Firstly, bile salts in the stomach were shown to cause alkaline gastritis, which may cause certain symptoms like burning epigastric pain, bilious vomiting, episodic nausea, and vomiting.^{36 37} Installation of intestinal contents into the residual gastric pouch produced similar symptoms supporting a role for the refluxed bile in their production.³⁸ Secondly, the amount of refluxed material is crucial to the development of these symptoms, and this may account for the development of these symptoms in some patients while they are absent in most patients.^{36 38} Thirdly, in several studies, the concentration of bile salts in the fasting gastric juice was found to be proportional to the net bile acid reflux per hour. So assessment of bile salt concentration at endoscopy can represent the degree of duodenogastric reflux during 24 hours.^{37 39} Fourthly, *H pylori* is strongly associated with type B gastritis causing occasionally symptoms like epigastric fullness, heartburn, nausea, and vomiting. Although these symptoms are non-specific, there is some evidence that *H pylori* related gastritis may cause them.^{4 6 7 9}

Accordingly, we can assume that, at least in some patients who develop dyspepsia after cholecystectomy, their symptoms are caused by increased duodenogastric reflux and alkaline gastritis. In others the amount of bile reflux may not be high enough to cause this type of gastritis but is sufficient to affect *H pylori* colonisation in the stomach. This may 'cure' *H pylori* related gastritis with improvement in symptoms.

To confirm this assumption we suggest that additional studies are done on the symptoms present in patients with gall stone disease before and after cholecystectomy, and the relation of this change in symptoms, if present, to the amount of bile reflux and *H pylori* in the stomach. If such a relation is established, it may help in the treatment of patients who have residual dyspepsia or develop new dyspeptic manifestations after cholecystectomy.^{40 41}

In conclusion, our study shows that duodenogastric reflux is considerably increased, and *H pylori* colonisation in gastric mucosa is decreased after cholecystectomy. If gastritis should conclusively be shown to cause dyspepsia, then these findings would help explain changes in the pattern of symptoms after cholecystectomy, and suggest lines of treatment in this group of patients.
