Ciprofloxacin decreases the rate of ethanol elimination in humans

J Tillonen, N Homann, M Rautio, H Jousimies-Somer, M Salaspuro

Abstract

Background—Extrahepatic ethanol metabolism is postulated to take place via microbial oxidation in the colon, mediated by aerobic and facultative anaerobic bacteria.

Aims—To evaluate the role of microbial ethanol oxidation in the total elimination rate of ethanol in humans by reducing gut flora with ciprofloxacin.

Methods—Ethanol was administered intravenously at the beginning and end of a one week period to eight male volunteers. Between ethanol doses volunteers received 750 mg ciprofloxacin twice daily.

Results—A highly significant ($p=0.001$) reduction in the ethanol elimination rate (EER) was detected after ciprofloxacin medication. Mean (SEM) EER was 107.0 (5.3) and 96.9 (4.8) mg/kg/h before and after ciprofloxacin, respectively. Faecal Enterobacteriaceae and *Enterococcus* sp. were totally absent after medication, and faecal acetaldehyde production capacity was significantly ($p<0.05$) decreased from 0.91 (0.15) to 0.39 (0.08) nmol/min/mg protein. Mean faecal alcohol dehydrogenase (ADH) activity was significantly ($p<0.05$) decreased after medication, but ciprofloxacin did not inhibit human hepatic ADH activity in vitro.

Conclusions—Ciprofloxacin treatment decreased the ethanol elimination rate by 9.4%, with a concomitant decrease in intestinal aerobic and facultative anaerobic bacteria, faecal ADH activity, and acetaldehyde production. As ciprofloxacin has no effect on liver blood flow, hepatic ADH activity, or cytochrome CYP2E1 activity, these effects are probably caused by the reduction in intestinal flora.

(Gut 1999;44:347-352)

Keywords: ciprofloxacin; ethanol; colonic bacteria; metabolism; alcohol dehydrogenase; acetaldehyde

The most important route of ethanol elimination is its metabolism in the liver, with small amounts excreted in the breath (0.7%), urine (0.3%), and sweat (0.1%).¹ Three principal hepatic enzyme systems are involved: alcohol dehydrogenase (ADH), the microsomal ethanol oxidising system (MEOS), and catalase.² It is generally agreed that the major part of ethanol is metabolised by cytosolic ADH.² The contribution of the MEOS to ethanol elimination is limited, and only a minor part (1-5%) of the total metabolism in vivo is carried out by the cytochrome P450 dependent MEOS.³

Liver catalase can oxidise ethanol in vitro, but under physiological conditions catalase appears to play only a minor role in ethanol metabolism.²

Extrahepatic elimination of ethanol does, however, also occur. To a smaller extent, ethanol is oxidised to acetaldehyde in other tissues possessing ADH activity, such as the stomach, small intestine, colon, kidneys, and lungs.⁴ In rats, the extrahepatic gastrointestinal metabolism of circulating ethanol has been shown to be up to 30% of that in the liver.⁵ Furthermore, in patients with cirrhosis of the liver, extrahepatic elimination has been estimated to constitute about 40% of the total ethanol elimination.⁶

Due to its high water solubility, ethanol levels inside the terminal ileum⁷ and colon⁸ are equal to those of the blood. We have recently shown in experimental animals that ethanol can be oxidised via the aerobic and facultative anaerobic bacteria in the large intestine.⁹ Most of the luminal bacteria are anaerobic, and without oxygen they are capable of producing energy through fermentation.¹⁰ In alcoholic fermentation the end product is ethanol, which is derived from acetaldehyde in a reductive reaction mediated by bacterial ADH.¹¹ However, oxygen diffuses through the colonic mucosa, and, accordingly, the human gut contains a mucosa associated microflora in which the number of aerobic and facultative anaerobic bacteria is almost comparable¹² to that of anaerobic bacteria. Under these conditions and in the presence of exogenous ethanol, the ADH mediated bacterial reaction can oxidise ethanol to acetaldehyde in a reaction in which nicotinamide adenine dinucleotide (NAD) acts as an electron acceptor.¹³ Microbial catalases, in the presence of H₂O₂, can also oxidise ethanol to acetaldehyde.¹⁴

Ciprofloxacin possesses excellent in vitro and in vivo antibacterial activities against most aerobic and facultative anaerobic bacteria, including Enterobacteriaceae.^{15,16} Furthermore, ciprofloxacin is partly eliminated through the intestinal wall,¹⁷ and the concentrations of ciprofloxacin in the faeces and intestinal mucosa are higher than the corresponding serum levels.¹⁸ This transintestinal elimination pattern may explain the ability of this drug to modify the colonic flora.

Treatment with ciprofloxacin was recently shown to reduce the rate of ethanol elimination by 9% in rats, and this was associated with a

reduction in faecal aerobic flora and faecal ADH activity.¹⁹ The aim of the present study was to evaluate the role of microbial ethanol oxidation in the total elimination of ethanol in man by reducing human gut flora with ciprofloxacin. The second aim was to study possible changes in faecal flora and faecal enzyme activities participating in both ethanol oxidation and acetaldehyde production before and after administration of ciprofloxacin for one week.

Materials and methods

SUBJECTS

After approval by the Ethical Committee at the University Central Hospital of Helsinki, eight healthy men, with an age range of 21–31 years participated in the *in vivo* studies. Mean body weight was 78 (3) kg, and body mass index 23.8 (0.4) kg/m². None of the subjects had received any antibiotics for four weeks preceding the study or was using any other drugs during the study days. One of the subjects was a light smoker. All were moderate consumers of alcohol, with a weekly average consumption of 70 g or less of ethanol. All participants were told to refrain from ethanol for at least 36 hours before the study.

STUDY DESIGN

A paired design in which each subject served as his own control was used (open, non-randomised, no placebo control). Two study days were separated by a one week interval. The volunteers were admitted to the University Central Hospital of Helsinki, and all studies started between 8 00 and 9 00 am. Two intravenous lines (Viggo, 1.22 mm/18 G L 32 mm, BOC Ohmeda AB, Helsingborg, Sweden) were placed into the antecubital veins at the beginning of each study day, one for the administration of ethanol and one for obtaining repeated blood samples. Ethanol (0.63 g/kg body weight) was mixed in 5% glucose solution at 7% concentration and was administered at a constant rate over a 30 minute period intravenously. This application was chosen to avoid the influence of the first pass metabolism and alterations in gastric motility on ethanol pharmacokinetics. Eating and smoking were prohibited during the study. Blood samples (3 ml) were taken into vacutainer tubes containing 0.06 ml EDTA for measurement of blood alcohol levels by head space gas chromatography. Baseline samples were taken before ethanol administration had started (time 0) and at five minute intervals during the first hour, at 15 minute intervals during the second hour, and at 20 minute intervals until the breath ethanol analyser (Lion Laboratories, Barry, UK) showed no detectable blood ethanol levels. The protocol was exactly the same on both study days. During the seven days between the experiments, the volunteers received 750 mg ciprofloxacin (Ciproxin, Bayer AG, Leverkusen, Germany) orally twice a day. The drug intake was started on the evening of the first infusion day and the last tablet was taken one hour prior to the administration of intravenous ethanol on the second study day.

Faecal samples were collected before and after medication, and samples were frozen to –80°C within six hours.

BACTERIAL ANALYSIS

The faecal samples were thawed, and 1 g of each specimen was suspended and serially diluted (10-fold) from 10⁻¹ to 10⁻⁶ in peptone yeast extract broth. Undiluted sample and a 10 µl aliquot of the appropriate dilutions were inoculated and spread on several selective and non-selective agar media for the enumeration and isolation of total counts and main groups of aerobic and anaerobic bacteria and yeasts. The aerobic plates were incubated at 35°C in an atmosphere containing 5% CO₂ for up to five days; anaerobic plates were incubated in anaerobic jars filled with the evacuation replacement method with mixed gas (90% N₂, 5% CO₂, 5% H₂) for seven days for the first inspection and up to 14 days for the final inspection. The sensitivity of this method was 3000 colony forming units (cfu)/g faeces. The bacteria were enumerated and identified by established methods.^{20, 21}

FAECAL ACETALDEHYDE PRODUCTION

To measure acetaldehyde production capacity, faecal samples were lyophilised for 24 hours (Micromodulyo 1.5K Freeze Dryer, RV5 Rotatory Vane Pump, Edwards High Vacuum Int., UK). Thereafter dried faecal samples were dissolved in 0.1 M potassium phosphate (KPO) buffer (pH 7.4) at a concentration of 20 mg/ml. To obtain supernatant, the solution was first homogenised (10 × 5 seconds, 1200 min⁻¹; Potter S Homogenizer, B. Braun Melsungen AG, Germany) and then sonicated (8 × 20 seconds, 20 kHz, Sonics & Materials, USA), surrounded by ice to avoid protein coagulation. This was followed by centrifugation of the sonicate at 100 000 *g* at 5°C for 60 minutes, and supernatant was collected and used for measurements. A 250 µl aliquot of supernatant was incubated for 60 minutes in closed glass vials with 50 µl ethanol/buffer mixture (final concentration 22 mM ethanol, 0.1 M KPO buffer, pH 7.4) at 37°C after adding different coenzymes. The coenzymes used were nicotinamide adenine dinucleotide (NAD; final concentration in the reaction mixture 3 mM) to activate ADH, glucose oxidase (GOX; final concentration 0.03 µmol/min) and glucose (final concentration 10 mM) to produce hydrogen peroxide (H₂O₂) and to activate catalase, or both. All the reagents were obtained from Sigma Chemical Co. (St Louis, Missouri, USA). Reactions were stopped by injecting 50 µl of 6 mol/l perchloric acid (PCA) through the rubber septum of the vial; the final volume in vials was 500 µl. Acetaldehyde was analysed using headspace gas chromatography as described previously.²² To control for non-enzymatic artefactual acetaldehyde formation from ethanol during the protein precipitation,²³ PCA was added simultaneously with ethanol into additional incubation vials (incubation time 0) and the revealed values were subtracted from acetaldehyde values obtained after the 60 minute incubation period. Acetaldehyde

production was related to the protein concentration of the supernatant determined by the method of Lowry *et al.*²⁴

FAECAL ENZYME ACTIVITIES

To measure ethanol oxidising enzymes, ADH and catalase, supernatant, prepared as above, was used. ADH activity of the supernatant was determined spectrophotometrically by following the reduction of NAD (final concentration 3 mM in 0.1 M KPO, pH 7.4) using 25 mM or 1.5 M ethanol (in KPO) at 37°C. Catalase activity of the supernatant was determined spectrophotometrically at 240 nm after the addition of 10 mM H₂O₂ at 37°C (in 0.1 M KPO, pH 7.4).²⁵ Enzyme activities were related to the protein concentrations of the supernatant.

HEPATIC ADH ACTIVITY

Human liver tissue was obtained from a patient undergoing surgery. Liver tissue was first homogenised in the ratio of 1:4 (in 0.1 M KPO, pH 7.4). The homogenate was then centrifuged at 1000 g at 4°C for 10 minutes, followed by centrifugation at 100 000 g at 5°C for 60 minutes to obtain cytosol. Cytosolic ADH activity was determined spectrophotometrically by following the reduction of NAD (final concentration 3 mM in 0.1 M KPO, pH 7.4) using 25 mM ethanol (in KPO). The effect of ciprofloxacin on ADH activity was tested by adding increasing drug concentrations (final concentrations 1, 10, 20 µg/l) to the buffer used.

PHARMACOKINETICS OF ETHANOL IN BLOOD

The concentration-time profiles of ethanol were evaluated according to zero order kinetics. This pharmacokinetic model assumes a rectilinear disappearance of ethanol from blood

after the absorption and distribution of the dose is completed. The y intercept of the regression line (C_0) is the concentration of ethanol in blood if the dose of 0.63 g/kg was distributed into total body water immediately after the infusion started. The ratio of dose of ethanol (g/kg) divided by the parameter C_0 is the apparent volume of distribution of ethanol (V_d). The ethanol elimination rate (EER) from the body was obtained by dividing the dose given (0.63 g/kg) by the estimated time of reaching zero concentration of ethanol in blood (time₀). The time₀ parameter corresponds to the x intercept of the concentration-time regression equation. The areas under the concentration-time profiles (AUCs) were determined by the trapezoidal method from the beginning of ethanol administration to the time when it was no longer detectable.

STATISTICAL ANALYSIS

The results are expressed as mean (SEM). The statistical significance of the differences before and after the ciprofloxacin intake was analysed by Student's paired *t* test. A *p* value of less than 0.05 was considered to be significant. The possible correlations were tested by using simple linear regression analysis.

Results

EFFECT OF CIPROFLOXACIN ON ETHANOL PHARMACOKINETICS

Figure 1 represents the mean (SEM) values of the concentration-time profiles of ethanol in blood and regression lines to the elimination phase of the curves for eight subjects. Table 1 summarises the pharmacokinetic parameters of ethanol derived from blood concentration-time data. The time to reach zero ethanol concentration in blood (time₀) increased after ciprofloxacin medication, and accordingly there was a highly significant decrease (*p*=0.001) in the EER. The mean (SEM) ethanol elimination rates were 107.0 (5.3) mg/kg/h before the ciprofloxacin treatment and 96.9 (4.8) mg/kg/h after treatment for one week. The overall decrease in EER was 9.4%. The individual rate of ethanol elimination decreased in all volunteers (fig 2). The highest decrease in EER was 17.6% and the lowest 5.1%.

EFFECT OF CIPROFLOXACIN ON FAECAL BACTERIA
Ciprofloxacin treatment for seven days produced a clear decline in the number of faecal aerobic bacteria from 1.1×10^8 cfu/g to 6.5×10^6 cfu/g ($p=0.04$, Wilcoxon signed rank test). Before drug intake, Enterobacteriaceae was the predominant aerobic flora present in every volunteer. *Enterococcus* sp. were found in five of the eight subjects. After ciprofloxacin these species totally disappeared from the stool samples. *Streptococcus* sp. were initially present in five subjects, *Staphylococcus* sp. in one, *Lactobacillus* sp. in three, and *Corynebacterium* sp. in four subjects. These bacteria responded variably, either disappearing in some cases, persisting in others, or even arising after medication. Yeasts were not originally present in any volunteer, but appeared at levels of 1.0×10^4 and 6×10^4

cfu/g in two subjects out of eight after ciprofloxacin administration. The total count of anaerobic bacteria declined slightly. This was mainly due to a drop in the number of *Bifidobacterium* sp., initially present in six subjects, and present after ciprofloxacin administration in three of eight subjects. Table 2 summarises the bacteriological results for the faecal samples.

EFFECT OF CIPROFLOXACIN ON FAECAL ENZYMES AND ACETALDEHYDE PRODUCTION

The mean ADH activity of the faecal samples measured before ciprofloxacin treatment was significantly ($p<0.05$) higher at both ethanol concentrations than that of the samples taken after treatment (table 3). The high ethanol concentration was used in order to saturate all microbial ADH isoenzymes. The catalase activity, however, remained unchanged after ciprofloxacin dosing (table 3). The acetaldehyde production capacity of the faecal samples also decreased significantly after ciprofloxacin treatment when NAD was used as a cofactor to activate ADH, but remained unaltered when glucose + glucose oxidase was used to activate catalase (table 4).

Ciprofloxacin did not have any significant in vitro effect on the activity of human hepatic ADH at the concentrations used. ADH activity was 100.3%, 98.9%, and 102.5% compared with the control samples without the drug, when 1, 10, and 20 μ g/l (final concentrations) of ciprofloxacin, respectively, were used.

Although the individual rate of ethanol elimination decreased in all subjects, no correlation could be found between the decrease in the individual EERs and the reduction in bacterial counts. On the other hand, there was a statistically significant positive correlation ($r=0.75$, $p<0.001$) between faecal ADH activity at 1.5 M ethanol and acetaldehyde production from ethanol.

Discussion

This study shows that treatment with ciprofloxacin for one week reduces the ethanol elimination rate in man by 9.4% without affecting the apparent volume of distribution. The intravenous administration of ethanol excludes the possible effects of altered gastric emptying and gastric first pass metabolism on ethanol pharmacokinetics.²⁶ Ciprofloxacin did not inhibit hepatic ADH activity in vitro in concentrations exceeding serum concentrations¹⁸ known to exist in the liver tissue during treatment.²⁷ Ciprofloxacin has, however, been reported to reduce the hepatic metabolism of coadministered xanthines, such as theophylline and caffeine, leading to increased serum concentrations and reduced elimination of these substances.²⁸ The mechanism behind this effect has been suggested to be the specific inhibition of CYP1A2 activity.²⁹ In addition, ciprofloxacin decreases cytochrome CYP3A4 mediated biotransformation, but it does not inhibit the metabolism of substrates that are specific for the CYP2E1 and CYP4A1 isoenzymes.³⁰ The isoenzyme CYP2E1 is the major contributor to the MEOS in humans,

although CYP1A2 has also been considered to play a role.³¹ Thus the inhibitory effect of ciprofloxacin on the ethanol elimination rate could at least partly be the consequence of the drug's interference with cytochrome mediated ethanol oxidation. The contribution of the MEOS to ethanol metabolism, however, is at most 5%.³ Hence it is obvious that possible interactions between ciprofloxacin and ethanol oxidising enzymes in the liver can explain only a small part of the reduction in the ethanol elimination rate. Hepatic metabolism of ethanol may also be reduced because of the changes in hepatic blood flow. Ciprofloxacin, however, has no effect on the clearance of indocyanine green, a dye highly extracted by the liver, which indicates a lack of effect on hepatic blood flow.³² Thus the decrease in ethanol elimination found in this study is unlikely to be the result of decreased hepatic blood flow.

It has been shown in earlier experiments that human colonic contents are capable of producing significant amounts of acetaldehyde when incubated with ethanol concentrations known to exist in the colon during social drinking.²² Furthermore, many aerobic Gram negative bacteria belonging to the family Enterobacteriaceae and representing normal colonic flora in man possess notable NAD dependent ADH activity, and are able to produce significant amounts of acetaldehyde when incubated in vitro with ethanol.³³ In vivo microbially derived ethanol oxidation and acetaldehyde production have been shown to occur in rats with a self filling diverticulum and concomitant bacterial overgrowth,³⁴ and in the colon of pigs.³⁵ These findings strongly suggest that intestinal microbes are able to oxidise ethanol by a bacteriocolonial pathway for ethanol oxidation.^{9 35 36}

The results of this study suggest that the decrease in ethanol elimination produced by ciprofloxacin is most probably due to the reduction in gut aerobic flora and the consequent inhibition of ethanol oxidation via colonic bacteria. The findings from the bacteriological analysis support this hypothesis. The species of the family Enterobacteriaceae, which has been shown to possess ADH activity and to produce acetaldehyde from ethanol in vitro,³³ disappeared from the stool after ciprofloxacin treatment. Also, *Enterococcus* species were absent after medication. The bacterial flora of the human large intestine forms an extremely complex ecosystem, and there is almost never empty territory in the gut. When one compartment of this ecosystem is disturbed, other bacterial strains grow and fill this bare area. As can be seen in this study, the number of *Lactobacillus* species, which have been shown to be able to metabolise ethanol to acetaldehyde poorly,³⁷ were unchanged. In addition, the number of *Staphylococcus* species were even more numerous after the medication. The growth of other aerobic microbes that are not capable of ethanol oxidation probably makes it impossible to find any correlations between the decrease in the individual EERs and the reduction in total bacterial counts.

This is the first study to show that human stool samples possess ADH and catalase activities and produce acetaldehyde from ethanol in vitro. The faecal ADH activity and acetaldehyde production capacity decreased significantly after ciprofloxacin treatment for one week, whereas catalase activity remained unaltered. Furthermore, there was a significant correlation between faecal ADH activity and acetaldehyde production. These results strongly suggest that ethanol oxidation by colonic bacteria in man is mainly due to ADH associated reactions.

Jokelainen *et al* recently reported a 9% ($p < 0.02$) reduction in ethanol elimination in rats after high dose ciprofloxacin treatment for four days, with a concomitant decrease in faecal aerobic bacteria and ADH activity; yet an acute intraperitoneal dose of ciprofloxacin 60 minutes prior to ethanol administration had no effect on the rate of ethanol elimination.¹⁹ This implies that ciprofloxacin itself and/or its metabolites have no effect on the hepatic clearance of ethanol in vivo in rats. Neither were rat hepatic ADH nor MEOS activities affected by the ciprofloxacin treatment. This animal study supports our present findings regarding humans. In contrast, another human study with ciprofloxacin (500 mg twice a day for three days) showed no effect on ethanol pharmacokinetics (AUC, EER, peak ethanol concentration) after an oral ethanol dose of 0.38 g/kg.³⁸ In that study, as well in the present one, the last dose of ciprofloxacin was taken one hour prior to the administration of ethanol. The explanation for these contradictory findings could be the notable interindividual variations ($\pm 20\%$) in ethanol elimination rates. In order to eliminate the effects of this variation we used a study design in which each volunteer served as his own control. This enables detection of small differences in EER that might be hidden in a placebo controlled study if the sample size is too small. An additional explanation is that in the earlier study the dosage of the drug was lower and the duration of medication shorter than in our study. Accordingly, it is possible that the elimination of colonic flora was not sufficient to reach the rate limiting threshold for bacterial ethanol oxidation. Due to a higher ciprofloxacin dose we cannot entirely rule out the possibility that other factors, such as interactions with cytochrome enzymes, might also have influenced the results.

Bacterial ethanol oxidation is a novel finding and of interest for the field of gastroenterology. It has been shown previously that intracolonic formed acetaldehyde is only poorly metabolised by colonic mucosa,^{39 40} and bacteria⁴¹ and that it can also be transported to the liver via portal circulation.⁴² There is evidence that a low dose of acetaldehyde delivered to rats in drinking water produces microvesicular fatty infiltration of the liver even in the absence of ethanol.⁴² Accordingly, acetaldehyde of extrahepatic origin (formed by bacterial ADHs from ethanol in the colon), may contribute to the pathogenesis of alcoholic liver disease. Furthermore, intracolonic formed acetaldehyde may increase intestinal

permeability,⁴³ and chronic alcoholism may alter the composition of gut flora.⁴⁴ These factors may lead to elevated blood endotoxin levels⁴⁵ and may thereby contribute to the pathogenesis of alcoholic liver disease,^{46, 47} suggesting the use of antibiotics in the treatment of such disease. Nevertheless, we cannot exclude the possibility that the bacteriocolonial pathway for ethanol oxidation may also protect the liver by decreasing its exposure to ethanol.

In conclusion, ciprofloxacin treatment decreases the ethanol elimination rate by 9.4% in man, with a concomitant decrease in faecal ADH activity and acetaldehyde production in vitro. Due to a lack of evidence that ciprofloxacin interferes with hepatic ethanol metabolism, our findings can be explained by the reduction in aerobic and facultative anaerobic bacteria in the lumen and mucosal surfaces of the human large intestine. These findings support evidence of the significant role of colonic bacteria in extrahepatic ethanol metabolism and acetaldehyde production in man. It further supports the new microbiological approach to the pathogenesis of alcohol related gastrointestinal diseases.
