HEPATITIS

Suppression of haematopoiesis during therapy of chronic hepatitis C with different interferon α mono and combination therapy regimens

Background: Treatment of chronic hepatitis C with interferon (IFN)- α and ribavirin has haematotoxic effects. We evaluated the effects of four different IFN/IFN-ribavirin treatment regimens on haematopoiesis.

Methods: Haematopoiesis was studied in 133 patients with chronic hepatitis C receiving IFN- α 2b alone (group A) or in combination with ribavirin (group B), pegylated IFN- α 2a (group C), or pegylated IFN- α 2b (group D) in combination with ribavirin.

Results: At week 4, haemoglobin levels were diminished in all groups receiving combination therapy. In the monotherapy group, haemoglobin decreased slightly after eight weeks. In all groups, haemoglobin remained diminished throughout therapy. In all patients, leucocytes (white blood cells) decreased after four weeks and remained low during treatment. Platelets (peripheral platelet count (PPC)) were decreased in all groups after four weeks and remained below baseline levels during therapy in group A, C, and D whereas in group B PPC recovered early and reached baseline levels at week 16 of therapy. Concomitantly with the decreases in haemoglobin and PPC, erythropoietin increased in all groups receiving combination therapy and thrombopoietin in all groups. Patients treated with pegylated IFN- α 2a and those who received pegylated IFN- α 2b combination therapy differed only in leucopoiesis, whereas erythropoiesis and thrombopoiesis were comparable.

Conclusion: IFN- α based therapies are associated with a decrease in all three haematopoietic lineages, irrespective of the type of therapy used. The stronger suppressive effect of pegylated IFN- α 2a on leucopoiesis could be due to a dose effect. Overall, concentrations of endogenous haematopoietic growth factors are increased but can only partially alleviate haematotoxicity. Potential uses of exogenous haematopoietic growth factors and their impact on the virological response need to be explored.

Chronic hepatitis C is a major cause of cirrhosis, end stage liver disease, and hepatocellular carcinoma.^{1–3} The current treatment of choice for chronic hepatitis C is combination therapy with interferon α (IFN- α) and ribavirin (RBV).^{4–5} Unfortunately, both drugs have significant haematological toxic effects.^{6–8}

IFN- α exerts antiproliferative effects on many cell types. These properties are used for treatment of chronic myeloproliferative and lymphoproliferative diseases^{9–10} but also account for several undesirable effects, such as thrombocytopenia and leucopenia, and can interfere with the successful clinical application of full dose IFN- α in patients with chronic hepatitis C.^{9–11}

IFN induced thrombocytopenia and leucopenia is common whereas anaemia is more a sequela of combination therapy with ribavirin.^{4–5, 8, 12–13} Thrombocytopenia is mild in most cases, amounting to a decrease in peripheral platelet count of 10–50% but, when severe, can lead to bleeding complications^{14–15} and discontinuation of IFN therapy.¹⁶ Absolute neutrophil and lymphocyte counts typically decrease by 30–50% of baseline values during IFN therapy but this is usually not associated with infection.^{17–18}

The main mechanism leading to cytopenia during IFN therapy seems to be bone marrow suppression by IFN- α .^{19–21} This suppressive action can be observed for pluripotent progenitor cells of all lineages.^{19–20} Immune mediated haematological toxicity²¹ and capillary sequestration of platelets and white blood cells²² have been proposed as additional causes for severe thrombocytopenia and leucopenia during IFN therapy.

Ribavirin treatment causes varying degrees of anaemia, presumably through haemolysis.^{12–13, 23} Discontinuation of IFN therapy usually leads to restitution of a normal complete blood count within several weeks.^{5–8} Dose reductions can improve haematological toxicities but carry the risk of a suboptimal treatment response.²⁴

To develop treatment strategies to improve adherence to IFN/RBV therapy, we studied the long term effects of IFN monotherapy and three different IFN/ RBV treatment regimens on the corpuscular elements of the blood, and on growth factors for thrombopoiesis and erythropoiesis in patients on antiviral therapy for chronic hepatitis C.

MATERIALS AND METHODS

Patients

A total of 133 patients with chronic hepatitis C participating in six prospective trials (table 1) with conventional IFN- α 2b (IntronA; Aesca-Schering Plough, Traiskirchen, Austria), pegylated IFN- α 2a (PEGASYS; Roche, Vienna, Austria), or pegylated IFN- α 2b (PegIntron; Schering-Plough, Kenilworth, New Jersey, USA) alone or in combination with ribavirin (Rebetol; Aesca-Schering Plough, Traiskirchen, Austria) were studied. Patient characteristics are shown in table 2.

Abbreviations: HCV, hepatitis C virus; IFN- α , interferon α ; RBV, ribavirin; WBC, white blood count; PPC, peripheral platelet count; EPO, erythropoietin; TPO, thrombopoietin; TIW, three times a week; BW, body weight; ANOVA, analysis of variance for repeated measurements; pegIFN, pegylated interferon; SOCS-1, suppressor of cytokine signalling 1

Table 1 Therapy regimens

Group	Interferon type and dose	Ribavirin dose (mg/day)	Duration of therapy (weeks)	n	Reference
A	5 MU IFN- α 2b TIW	—	36	26	(Datz C, unpublished data), Ferenci ²⁵
B	5 MU IFN- α 2b TIW	1000–1200	38	32	Ferenci ²⁶
C	180 μ g 40 kDa pegylated IFN- α 2a/week	1000–1200	48	41	(Ferenci P, unpublished data), Fried ²⁷
D	1.5 μ g/kg 12 kDa pegylated IFN- α 2b/week	1000–1200	24	34	(Ferenci P, unpublished data)

IFN- α , interferon α ; TIW, three times a week.

The protocols conformed to the ethical guidelines of the 1975 Declaration of Helsinki in its most recent form and were approved by the institutional review committee of the University of Vienna Medical Faculty. Informed written consent was obtained from each patient before entry into the study.

Blood for measurements of all parameters was obtained on day 0 (before IFN therapy), and at weeks 4, 8, 12, 16, 20, 24 (all groups), 36 (groups A, B, and C), and 48 (only group C) after beginning IFN therapy. All patients were followed up one and six months after the end of IFN therapy.

Measurements

Hepatitis C viral load was determined by Cobas Amplicor HCV Monitor version 2.0 (Roche Diagnostics, Branchburg, New Jersey, USA).

Prothrombin time was measured as a percentage of a reference sample to account for variabilities in absolute values (seconds) between batches of reagents ("Normotest"; normal range 75–120%) which has been shown to be the most reliable test of global coagulation in liver disease.³⁰

TPO enzyme linked immunosorbent assay and EPO enzyme linked immunosorbent assay

Serum levels of thrombopoietin (TPO) and erythropoietin (EPO) were measured using the Quantikine human TPO and EPO enzyme linked immunosorbent assay (ELISA; R&D Systems, Abingdon, UK). Both assays were performed according to the manufacturer's instructions, as previously described.^{8, 31}

Statistical analysis

Statistical analysis was performed using STATISTICA for Windows v.5.1 (Statsoft Inc., Hamburg, Germany). The Wilcoxon matched pairs test was used for within patient comparisons between pre-IFN therapy values and individual time points during therapy. Differences between different patient groups were analysed using the Mann-Whitney U test. A *p* value <0.05 was considered statistically significant.

RESULTS

Erythropoiesis during IFN therapy

After four weeks of IFN- α therapy, haemoglobin levels decreased in the patient groups receiving combination therapy (median values: group B, 10%; group C, 20%; group D, 13%; *p*<0.001) but not in patients receiving monotherapy. After eight weeks, haemoglobin levels decreased slightly in patients receiving monotherapy (group A, 5%; *p*<0.05) (fig 1, table 3). In the following weeks of treatment haemoglobin levels remained below baseline in all groups, with a maximum decrease of 5% in group A at weeks 12 and 20, 16% in group B at week 20, 22% in group C at week 48, and 19% in group D at weeks 16 and 20 (fig 1, table 3). In the first 24 weeks of therapy (duration of therapy in group D), a haemoglobin level below 11 g/dl occurred in 15%, 38%, 46%, and 44% of patients in groups A, B, C, and D, respectively (group A *v* group C, group A *v* group D, *p*<0.05; group A *v* group B, group B *v* group C, group B *v* group D, group C *v* group D, NS) and a decline in haemoglobin below 10 g/dl was found in 6% of patients in group B, in 29% in group C, and in 15% in group D (group B *v* group C, *p*<0.05; group B *v* group D, group C *v* group D, NS).

In six patients in group B (19%), 15 patients in group C (37%), and 10 patients in group D (29%) the ribavirin dose was reduced (group B *v* group C, group B *v* group D, group C *v* group D, NS). Two patients in group B, 11 patients in group C, and four patients of group D received less than 80% of their scheduled dose of RBV (group B *v* group C, *p*<0.05; group B *v* group D, group C *v* group D, NS). Consequently, patients in group B received an average of 99% of the planned dosage (1054 (633–1200) mg of 1069 (800–1200) mg), patients in group C received 94% (1041 (358–1200) mg of 1112 (800–1200) mg), and patients in group D received 96% of the anticipated dose (980 (508–1200) mg of 1024 (800–1200) mg) over the whole therapy period. Haemoglobin did not decrease below 8.5 g/dl in any patient.

After termination of treatment, haemoglobin levels increased rapidly and returned to baseline after four weeks in group A and after 24 weeks in group B. In groups C and D,

Table 2 Patient characteristics

	Group A	Group B	Group C	Group D
Sex (M/F)	15/11	23/9	24/17	18/16
Age (y)	42 (19–65)	37.5 (20–50)	44 (26–64)	43.4 (21–64)
Weight (kg)	79 (51–92)	72 (50–95)	78 (51–103)	72 (48–100)

†Patients coinfecting with different hepatitis C virus (HCV) genotypes (group A, one; group B, two; group C, three; group D, three).

‡No data available for group A.

§No biopsy obtained (group A, five; group B, four; group C, five).

Figure 1 Erythropoiesis. Haemoglobin level (A), erythropoietin level (B), and reticulocyte count (C) before (week 0), during (week 4 until the end of therapy (EOT)) and after (week 4p and week 24p) therapy with conventional interferon α (IFN- α) alone (group A), in combination with ribavirin (group B), with pegylated IFN- α 2a (group C), or with pegylated IFN- α 2b in combination with ribavirin (group D). Data are mean (SEM).

haemoglobin levels also increased significantly after discontinuation of therapy but did not reach baseline levels within the study period (group C, 4%; group D, 3% below baseline at week 24 after therapy) (fig 1, table 3). As expected, the decrease in haemoglobin levels was more severe in patients receiving combination therapy with RBV than in those receiving IFN- α alone (group A *v* group B, group A *v* group C, group A *v* group D, $p < 0.05$ at any week of therapy) (fig 1). Patients in groups B, C, and D showed comparable decreases in haemoglobin levels with significant differences only at the beginning of therapy (group B *v* group C, group B *v* group D, $p < 0.05$ at week 4, NS at any other week of therapy; group C *v* group D, NS at any week of therapy; fig 1).

EPO levels increased by a median of 9% in group A ($p = 0.5$), 119% in group B ($p < 0.001$), 385% in group C ($p < 0.0001$), and 272% in group D ($p < 0.0001$) at week 4 (fig 1, table 3). Within the next weeks of therapy, EPO levels further increased in patients receiving combination therapy ($p < 0.001$ for any week of therapy), group B reaching maximum EPO levels at week 16 (median increase 520%, $p < 0.001$), group C at week 20 (median increase 543%, $p < 0.0001$), and group D at week 24 (median increase 353%, $p < 0.0001$). In the groups receiving combination therapy, EPO levels remained significantly above baseline values throughout the whole therapy. In group A, receiving IFN- α

alone, EPO levels increased significantly only at the end of treatment (median increase in group A, 131%; $p < 0.05$ at week 36). After discontinuation of therapy, EPO levels returned to baseline within four weeks in groups A and D and within 24 weeks in group B, while in group C EPO levels were still elevated at the end of follow up (group C: 65% above baseline at week 24 after the end of therapy) (fig 1, table 3).

EPO levels differed between patients receiving combination therapy or monotherapy (group A *v* group B, $p < 0.05$ for weeks 8 to end of therapy; group A *v* group C, group A *v* group D, $p < 0.05$ for any week of therapy) Except at week 4, the increase in EPO levels was similar in patients on combination therapy (group B *v* group C, group B *v* group D, $p < 0.05$ at week 4, NS at any other week of therapy; group C *v* group D, NS at any week of therapy) (fig 1).

The reticulocyte count as a measure of bone marrow regenerative activity of erythroid progenitor cells was increased after four weeks of treatment in groups B, C, and D (median increase in group B, 41%; group C, 58%; group D, 45%; $p < 0.01$) (fig 1, table 3). In patients in group C, the reticulocyte count decreased again after week 4 reaching baseline levels at week 24 of therapy despite continuously decreased haemoglobin levels and markedly compensatory increases in EPO levels, whereas in patients in groups B and D the reticulocyte count remained elevated compared with baseline values throughout the therapy (group B, $p < 0.001$; group D, $p < 0.05$ for any week of therapy) with a maximum increase of 102% at week 12 in group B and 45% at week 4 in group D. Reticulocyte count in groups B and D returned to baseline at week 24 after the end of treatment (fig 1, table 3). Starting at week 8, patients in group B showed significantly higher levels of reticulocytes than those of groups C and D (Mann-Whitney U test: $p < 0.05$ for week 8 until the end of therapy) (fig 1). Patients with or without liver cirrhosis did not differ in their erythropoietic response to IFN mono or combination therapy (NS).

Thrombopoiesis during IFN therapy

At week 4 of therapy, peripheral platelet count (PPC) decreased in all groups (median decrease in group A, 25%; group B, 8%; group C, 21%; group D, 23%; $p < 0.05$ for all groups) (fig 2, table 3). In group B, PPC increased again after week 12, reaching baseline values at week 16, and remained above baseline levels until the end of therapy. In the other three groups, PPC remained decreased throughout therapy, with a nadir of 34% in group A at week 16, 36% in group C at week 8, and 24% in group D at week 12. Platelets returned to baseline levels within four weeks after discontinuation of therapy in these groups (fig 2, table 3). The decrease in PPC was comparable between groups A, C, and D (Mann-Whitney U test: NS throughout therapy), and groups B and D (group B *v* group D, $p < 0.05$ at week 20, NS for any other week of therapy). Patients in group B showed significantly higher PPC levels than those of groups A and C (group A *v* group B, $p < 0.05$ for weeks 4–20; group C *v* group B, $p < 0.05$ for week 8 to end of therapy) (fig 2).

After four weeks of treatment, thrombopoietin (TPO) levels increased by a median of 32%, 2%, 49%, and 48% in group A ($p < 0.001$), group B ($p < 0.05$), group C ($p < 0.0001$), and group D ($p < 0.001$), respectively (fig 2, table 3). Within the next weeks of therapy, TPO levels further increased in all groups, reaching maximum levels at the end of therapy (median increase in group A, 58%, $p < 0.05$; group B, 82%, $p < 0.0001$; group C, 194%, $p < 0.0001$; group D, 117%, $p < 0.0001$). In all groups TPO levels remained elevated throughout the treatment ($p < 0.05$ for any week of therapy). After discontinuation of therapy, TPO levels returned to baseline within four weeks in group A and within 24 weeks in group B, while in groups C and D TPO levels were still

Table 3 Haematological changes during inteferon treatment for chronic hepatitis C

Values are medians (ranges).
Values in bold typeface indicate significant difference from pre-IFN treatment values ($p < 0.05$, Wilcoxon matched pairs test).
IFN, interferon; EPO, erythropoietin; TPO, thrombopoietin.

elevated at the end of follow up (group C, 43%; group D, 47% above baseline at week 24 after the end of therapy) (fig 2, table 3), even though platelet counts had returned to normal.

Figure 2 Thrombopoiesis. Platelet (A) and thrombopoietin (B) levels before (week 0), during (week 4 until the end of therapy (EOT)) and after (week 4p and week 24p) therapy with conventional interferon α (IFN- α) alone (group A), in combination with ribavirin (group B), with pegylated IFN- α 2a (group C), or with pegylated IFN- α 2b in combination with ribavirin (group D). Data are mean (SEM).

At baseline and week 4, patients in group A had higher TPO levels than those in group C ($p < 0.05$). Later on, throughout the whole treatment period, TPO levels were comparable between all four groups (Mann-Whitney U test, NS) (fig 2). In group A, PPC was lower in patients with liver cirrhosis compared with patients without cirrhosis (Mann-Whitney U test: $p < 0.05$ for week 0 to week 24) but TPO levels did not differ. In patients in group B, C, and D, the effects of IFN on thrombopoiesis were comparable between those with or without liver cirrhosis.

White blood count during IFN therapy

White blood count (WBC) was decreased in all groups after four weeks of therapy (median decrease in group A, 26%; group B, 31%; group C, 50%, group D, 44%; $p < 0.05$ for group A, $p < 0.0001$ for groups B, C, and D) and remained decreased throughout treatment (group A, $p < 0.05$; groups B, C, and D, $p < 0.0001$ for any week of therapy), with a maximum drop of 37% in group A at the end of therapy, 39% in group B at week 16, 55% in group C at the end of therapy, and 52% in group D at week 12. After termination of treatment, WBC returned to baseline within 24 weeks in all treatment groups (fig 3, table 3). The decrease in WBC levels was more severe in patients in group C than in those in groups A, B, and D (group A ν group C and group B ν group C, $p < 0.01$ at any week of therapy; group C ν group D, $p < 0.05$ at weeks 4, 8, and end of therapy), and in patients in group D compared with those in group A (group A ν group D, $p < 0.01$ at week 4 to week 20). Patients in groups A and B and those in groups B and D showed comparable decreases in WBC levels (group A ν group B, $p < 0.05$ at week 8 and 12, NS at any other week of therapy; group B ν group D, $p < 0.05$ at week 20, NS at any other week of therapy) (fig 3).

The decrease in WBC affected both neutrophils and lymphocytes. At week 4 of therapy, levels of both cell types

Figure 3 Leucopoiesis. Leucocyte count (A), neutrophil count (B), and lymphocyte count (C) before (week 0), during (week 4 until the end of therapy (EOT)) and after (week 4p and week 24p) therapy with conventional interferon α (IFN- α) alone (group A), in combination with ribavirin (group B), with pegylated IFN- α 2a (group C), or with pegylated IFN- α 2b in combination with ribavirin (group D). Data are mean (SEM).

decreased in patients on combination therapy (median decrease in neutrophils in group B, 40%; group C, 56%; group D, 55%; lymphocytes, group B, 14%; group C, 35%; group D, 27%; $p < 0.0001$). The decrease in neutrophils and lymphocytes in patients in group A was only marginal (median decrease in neutrophils 22%, lymphocytes 9%; Wilcoxon matched pairs test, NS) (fig 3). In patients on combination therapy both neutrophils and lymphocytes remained decreased throughout treatment. Groups B, C, and D reached the nadir of neutrophil count at week 8 (median decrease in group B, 40%; group C, 55%; group D, 49%) while lymphocytes continued to decrease and reached their nadir at week 16 in group D and at the end of treatment in groups B and C (median decrease in group B, 53%; group C, 62%; group D, 50%) (fig 3). After the end of treatment, neutrophil counts returned to baseline levels within four weeks in group D and within 24 weeks in groups B and C. Lymphocyte counts returned to baseline levels within 24 weeks after the end of treatment in groups B and D but remained below baseline levels in patients in group C at the end of follow up (median 12% below baseline at week 24 after therapy) (fig 3). However, the increase in lymphocyte counts in group C from the end of treatment until the end of follow up was significantly higher than in the other groups

(median increase in group A, 32%; group B, 80%; group C, 128%; group D, 72%; $p < 0.05$)

The decrease in neutrophil counts was comparable between groups A, B, and D, showing significant differences only at the beginning of therapy (group A ν group B, group A ν group D, $p < 0.05$ for weeks 4 and 8, NS for any other week of treatment; group B ν group D, NS for any week of therapy). Compared with groups A, B, and D, neutrophil count was lower in group C throughout the whole therapy (group A ν group C, group B ν group C, group C ν group D, $p < 0.01$ for any week of therapy) (fig 3). The decrease in lymphocyte count was comparable between groups A, B, and D (group A ν group B, group A ν group D, $p < 0.05$ at week 16 of therapy, NS at any other week of therapy; group B ν group D, NS for any week of therapy) but was significantly lower in group C than in groups A, B, and D (group A ν group C, $p < 0.05$ at any week of therapy; group B ν group C, $p < 0.05$ at week 16 until the end of therapy; group C ν group D, $p < 0.05$ at week 4, week 24, and at the end of therapy, NS at any other week of therapy) (fig 3). IFN therapy did not affect leucopoiesis differently in patients with liver cirrhosis compared with those without cirrhosis (NS).

DISCUSSION

Administration of both standard or pegylated IFN- α alone or in combination with ribavirin causes a significant decrease in all three lineages of the haematopoietic system, which cannot be completely counteracted by the endogenous production of haematopoietic growth factors.^{8 16 32} The mechanisms responsible for induction of cytopenia during IFN therapy have been studied in detail in vitro. Direct inhibition of progenitor cell proliferation in the bone marrow seems to be the dominant factor.^{19 20 33} In this study the effect of four treatment regimens on haematopoiesis was distinct. Haemoglobin levels were significantly diminished only in those patients receiving combination therapy with ribavirin, which accumulates in red blood cells and causes alterations in the erythrocyte membrane known to be associated with erythrophagocytic extravascular destruction and haemolysis.^{7 23}

Although reticulocytes increased significantly in all groups receiving combination therapy, the increase was inadequate to overcome the effects of IFN/ribavirin combination therapy, despite significantly elevated EPO levels. This confirms the suppressive action of IFN- α on erythroid progenitor cell proliferation.^{10 19 20} Long acting peginterferons appear to exert a more pronounced suppressive effect as reticulocytes were significantly higher despite less pronounced anaemia and similar EPO levels in patients treated with the conventional IFN/ribavirin (group B) compared with groups C and D. In patients who received pegylated IFN, haemoglobin levels had not returned to baseline at the end of the study period while in those in group B, haemoglobin values reached baseline 24 weeks after the end of therapy.

Possibly the most interesting clinically relevant question is whether the side effects of the different regimens require dose modifications during therapy with direct impact on clinical outcome such as sustained viral response. While this study clearly does not have the power to answer this question, there are some clues which will need to be pursued in larger analyses: even though no direct differences between the two pegylated IFNs could be demonstrated with regard to decrease in haemoglobin levels, ribavirin dose reductions, or patients who received less than 80% of the scheduled dose, there were significantly more patients who received 40 kDa-PegIFN- α 2a (group C) who had a haemoglobin level < 10 g/dl and who received $< 80\%$ of their scheduled dose compared with the conventional IFN/ribavirin group (group B). No difference between group B and group D was observed for these parameters.

In all treatment groups the endogenous physiological increase in EPO was unable to counteract the adverse effects of IFN/RBV. Correction of anaemia could result in better adherence to combination therapy, which may lead to improved sustained virological response rates. Potential strategies include treatment with antiviral agents that do not cause significant haemolysis, such as levovirin or viramidine, or support with haematopoietic growth factors. Recent data show that treatment with superphysiological doses of recombinant EPO can positively impact erythropoiesis, by correcting anaemia and thereby permitting maintenance of patients' intended ribavirin dose.^{34–38}

PPC was significantly reduced in all groups after four weeks of treatment. The significant increase in TPO levels paralleling the decrease in platelet count indicates a true reduction in platelet number, because TPO is produced at a constant rate and regulated through clearance by c-mpl receptors on platelets and megakaryocytes.^{39–40} The decrease in PPC by IFN- α is caused by diminished production of platelets through suppression of megakaryocyte progenitor cell proliferation and differentiation in bone marrow,^{9–10,20} as shown previously. The median increase in TPO levels (48–117%) was not as high as one would expect, considering the exponential increase in TPO levels with declining platelet count,⁴¹ and seems to confirm previous findings of a blunted TPO response to thrombocytopenia during IFN therapy.³²

The inability of increased TPO serum levels to sufficiently counteract the decrease in platelet production could also be explained by induction of suppressor of cytokine signalling 1 (SOCS-1) by IFN- α .^{9,42} Irrespective of the underlying mechanism, the increase in endogenous TPO was insufficient to counteract the impact of therapy in groups A, C, and D. Combination therapy with ribavirin did not cause a further decrease in PPC, as previously described,⁵ and PPCs even increased after an initial drop in patients receiving standard IFN combined with ribavirin (group B). The mechanism seems to be the combined effects of elevated TPO and EPO levels on megakaryocytic progenitor cell proliferation.^{43–44} EPO levels were significantly higher during combination therapy with ribavirin compared with IFN monotherapy because of the stimulus triggered by haemolytic anaemia.⁴⁵ However, in patients receiving pegylated IFN and ribavirin, the combined effects of high TPO and EPO serum levels were not able to overcome the suppressive action of pegIFN on thrombopoiesis. This is likely because of a stronger and continuous suppressive effect of pegylated IFN on progenitor cell proliferation compared with standard IFN. Again, as shown for erythropoiesis, pegylated IFN- α 2a seems to exert a slightly stronger suppressive effect on thrombopoiesis compared with pegylated IFN- α 2b.

The two groups treated with long acting peginterferons did not differ with regard to their PPC levels but did differ compared with the conventional IFN/ribavirin group B. Leucocytes decreased and remained below baseline levels throughout the whole treatment period in all groups (fig 3). The decrease in WBC in the monotherapy group was only marginal. Both pegylated IFNs exerted a stronger suppressive effect on leucopoiesis compared with monotherapy with conventional IFN, but compared with group B, only group C showed a significantly stronger suppression of WBC. When the two peg-IFNs were directly compared, patients treated with IFN- α 2a showed lower WBC counts at weeks 4 and 8, and at the end of therapy.

Neutrophil and lymphocyte counts were the only parameters with a clearcut statistically significant difference between the two peginterferon preparations. Throughout the whole of the treatment period, patients in group C had significantly lower levels of neutrophils compared with patients in group D. The difference in lymphocyte counts

between the two groups could only be seen at week 4, at the end of therapy, and at the end of follow up. While the difference at the end of therapy can be explained by the difference in treatment duration between these groups, the difference in WBC and lymphocyte counts at the beginning of therapy and neutrophil counts throughout the treatment period could be attributed to different pharmacological properties. Whether this is due to different biological properties of the modified interferon molecules or an effect of dose accumulation of the 40 kDa-PegIFN- α 2a compared with the 12 kDa-PegIFN- α 2b cannot be determined with certainty. The fact that despite similar antiviral activities there was a clearcut difference in leucopoiesis and a similar trend in erythropoiesis and thrombopoiesis in favour of the 12 kDa-PegIFN- α 2b still provides no clear mechanistic distinction but argues in favour of at least some biological differences between these drugs.

Another interesting fact is that only in patients in group C did lymphocytes not return to baseline levels at the end of the study period. Most likely this can be explained by the longer duration of therapy in this group. An irreversible effect of pegIFN- α 2a is unlikely as patients in group C showed the highest increase in lymphocyte counts from the end to therapy until the end of follow up, and as lymphocyte counts were within the normal range at the end of the study period the clinical relevance of this observation is questionable.

In summary, the haematological toxic effects of combination antiviral therapy with IFN/ribavirin occur in association with a marked increase in endogenous growth factor levels of EPO and TPO. Yet these marked increases are still insufficient to counteract the side effects to an extent that would allow all patients to receive full dose antiviral therapy.

There is evidence that patients with marked haematological toxicities will benefit from treatment with superphysiological doses of specific haematopoietic growth factors,^{7,35,38,46–48} enabling them to receive full dose combination therapy. Whether this can ultimately improve sustained virological response rates remains to be established in prospective randomised trials. These trials should provide the answer to the important question of whether expensive growth factor therapy in addition to full dose antiviral therapy will become an accepted and worthwhile alternative to dose reduction of antiviral therapy.
