The agglutinating antibody response in the duodenum in infants with enteropathic *E. coli* gastroenteritis

A. S. McNEISH, N. EVANS, H. GAZE, AND K. B. ROGERS

*From the Institute of Child Health, University of Birmingham, and the Department of Microbiology, Birmingham Children’s Hospital*

**Summary** The agglutinating antibody responses in duodenal fluid and serum were measured serially in 15 infants with enteropathogenic *E. coli* gastroenteritis. Peak levels of duodenal agglutinins were recorded eight to 18 days after the onset of symptoms, and the titres fell within the next seven to 14 days. These antibodies were mainly of the IgA class but IgM antibodies were detected early in the response, especially in the youngest infants.

Serum antibody responses were detected in eight patients, but they correlated poorly with the titres of intestinal antibodies. No rise in serum antibodies was found in six infants. Further studies are required to determine whether these differences are host-derived or whether they reflect different pathogenic properties of the infecting organisms.

The importance of the secretory immune system as a defence mechanism has been well documented in man and animals (Tomasi, 1970). However, there have been few studies of the antibody response to *Escherichia coli* in the intestine of the human infant, especially during natural infections. Girard and Kalbermatten (1970) immunized orally a group of infants, using an antigenic preparation of 11 strains of *E. coli*, and found agglutinating antibodies in the duodenal fluid eight to 44 days later. Lodinova and Wagner (1970) and Lodinova, Jouja, and Wagner (1973) demonstrated specific coproantibodies in normal infants after colonization of the upper intestine by non-pathogenic *E. coli* 083 with an associated increase in both IgA and IgM in the stools.

We have extended our previous studies (McNeish and Gaze, 1974; McNeish, Gaze, and Evans, 1974) on acute enteropathogenic *E. coli* gastroenteritis in infants by measuring the agglutinating antibody response in the duodenal fluid and serum during natural infection. We have also tried to determine the immunoglobulin (Ig) class of the intestinal antibodies.

**Patients and Methods**

**Clinical**

Fifteen infants aged from 5 weeks to 15 months presented with acute diarrhoea and vomiting of one to five days’ duration. *E. coli* of serotypic strains commonly associated with acute enteritis was isolated from the stools of each child during the acute phase of the illness and was not isolated after recovery. The O serotypes were 026(1), 044(1), 055(1), 0112(1), 0114(6), 0119(2), 0126(1) and 0128(2). All infants were treated by fluid replacement and regrading of feeds. None had antibiotics, and clinical recovery was complete within three to 10 days in each case.

**Duodenal fluid specimens**

These were obtained by peroral intubation after a fast of from four to six hours. They were taken onto ice at 4°C, centrifuged at 8000 g for 15 minutes to remove debris and bacteria, stored at -20°C, and studied within 48 hours. Duodenal fluid and serum were obtained from each infant as soon as the diagnosis was established and again four to 14 days later.

**Bacterial agglutination**

In each case, the strain of *E. coli* to be used was obtained from the infant’s faeces during the acute illness. A heat-killed suspension of the organism in phosphate-buffered saline (pH 7.2) was used at an optical density of 0.4 at 600 nm. Doubling dilutions of duodenal fluid or serum were incubated in microtitre trays at 4°C for 16 hours before reading. Autoagglutination was considered to be excluded...
by negative saline controls and the consistent titres obtained with each suspension of organisms against commercial typing antisera (Wellcome).

**IMMUNOGLOBULIN CLASS OF AGGLUTINATING ANTIBODIES** (modified from Reed and Williams, 1971)

Monospecific sheep antihuman-IgG, -IgA and IgM antisera (generously supplied by Professor P. G. H. Gell) were absorbed with *E. coli* of the above serotypes to remove agglutinating anti-*E. coli* antibodies. Absorptions were repeated until no agglutination could be obtained using neat serum. An amount of antiserum (usually 0.5-2 volumes) sufficient to precipitate specific immunoglobulin was added to 0.5-ml volumes of duodenal fluid, incubated at 37°C for one hour and centrifuged at 14000 g for 45 minutes. The antisera were of known antigen-binding capacity; residual immunoglobulin in the supernatants was not measured. A reduction in bacterial agglutination titre of 2 dilutions or more in the supernatant was taken to indicate the presence of agglutinating antibody of the appropriate Ig class. Absorbed non-immune sheep serum was used in control experiments.

**Results**

**AGGLUTINATING ANTIBODIES IN DUODENAL FLUID**

These are illustrated in figure 1. Antibodies were detected in all but one patient at the initial examination. Rising antibody titres were found until eight to 18 days after the onset of symptoms, and falling titres were recorded after 10 to 27 days.

**SERUM AGGLUTINATING ANTIBODIES**

These were measured in all but one infant and are illustrated in figure 2. In six children, no agglutinin response was detected. Eight children had agglutinating antibodies in their sera, but the character of the response was much more varied compared with the duodenal response. The possible significance is discussed later.

Table: Immunoglobulin classes of duodenal agglutinating antibodies

¹Log₁₀ agglutination titres remaining after absorption of duodenal fluid with Ig-class-specific antisera.

²Brackets signify equivocal responses.

IG CLASS OF AGGLUTINATING ANTIBODIES IN DUODENAL FLUID

The available results on six patients are shown in the table. IgA antibodies were detected in all patients at some stage. IgM antibodies were detected in five and appeared to be the predominant antibodies in two. In two patients, IgG antibodies were also found.

Discussion

In 10 of the 15 cases, the episode of gastroenteritis occurred as part of an outbreak, either within a family, or in a closed ward. The same E. coli serotype was isolated from each member of the group during the acute illness, and was not found after recovery. These observations, and the specific antibody responses discussed below, suggest strongly that the organisms were truly enteropathogenic, even though we did not attempt to measure enterotoxin production by these strains (Gorbach, 1970).

The antibody response to E. coli in the upper gut has been studied in animals and, less extensively, in human subjects. Porter, Noakes, and Allen (1970) instilled heat-killed E. coli into Thiry-Vella loops of jejunum in young pigs, and demonstrated agglutinating antibodies that appeared within three to four days, reached a peak around 10 days, and fell to low levels by 20 days. In mice infected with E. coli 0127, Kenny, Woleslagle, Gray, Michaels, and Pearson (1970) detected coproantibodies in adult animals that reached a peak around 30 days. No coproantibody response was found in infant mice. Lodinova et al (1970, 1973) allowed non-pathogenic E. coli 083 to colonize the upper intestine of normal human infants. Agglutinating coproantibodies were detected in the stools within one week, reached a peak at four weeks, and subsided slowly between 10 weeks and six months. This approximated closely to the time during which the bowel was colonized by E. coli 083. GIRARD and Kalbermatten (1970) immunized a group of infants orally with an extract of 11 strains of E. coli. Agglutinating antibody titres in the duodenal fluid were high by eight to 12 days and persisted for up to 44 days.

The pattern of response of duodenal agglutinins in the present study most closely resembles the data of Porter et al (1970). Variations in antigenic dose and persistence may explain the differences in other studies.

In many studies of intestinal antibodies, the role of IgA is rightly emphasized (Tomasi, 1970). However, antibodies of other immunoglobulin classes may be important, and differences may relate to species, age, type of antigen, or methods used to determine the immunoglobulin class of the antibodies.

In the young pig, Allen and Porter (1973) found that there were as many IgM as IgA cells in the lamina propria of the small intestine, although IgA was the predominant class of antibody produced in response to E. coli 0141 (Porter et al, 1970). In the unweaned calf, IgM is the major immunoglobulin class in the jejunal fluid (Porter, Noakes, and Allen, 1972). In rabbits infected with Trichinella, Crandall, Cebra, and Crandall (1967) found an increase in IgM cells in the gut lumina seven to 13 days after infection, with a later rise in IgG. The IgA cell count remained high throughout the infection. By indirect immunofluorescence most antibodies were of the IgG class.

Studies of human patients with enteric bacterial infections have given results that agree broadly. Northrup and Hossain (1970) investigated 10 adult patients with cholera and found that jejunal anti-
bodies of IgA and IgM classes were produced during the course of the illness. IgG antibodies in serum and jejunum were high from the beginning of the illness and presumably were the result of previous infection. IgM and later IgA antibodies were detected in the sera. Reed and Williams (1971) studied 14 adults with shigellosis. IgA was the major immunoglobulin in stool fluid. Determination of the immunoglobulin class of the antibodies (using a technique similar to that used in the present study) indicated IgA antibodies in two, IgM antibodies in three, IgM and IgA antibodies in two, IgA and IgG antibodies in one, and all three classes of immunoglobulin antibodies in one patient. Girard and Kalbermatten (1970) measured the production of antibodies in the duodenal fluid of 12 infants eight to 44 days after oral immunization with extracts of 11 strains of E. coli. Agglutinating antibody titres had a geometric mean of 17-2, with virtually zero values for controls. The antibodies were of IgM class at eight to 12 days, and were IgA (± IgM) at 22 to 32 days. No serum antibodies were detected.

Lodinova et al (1973) observed the development of faecal immunoglobulins and coproantibodies in groups of infants after oral colonization with E. coli 083. IgA and to a lesser extent IgM were found in the stools. Haemagglutination titres rose over the first four weeks to approximately 1:32 and persisted at this level for 16 weeks, during which time E. coli 083 remained dominant in the bowel flora. Antibody titres in the stools appeared sooner than in serum.

Our observations confirm that IgA-coproantibodies are found at the height of the response in infants but suggest that IgM antibodies may be important perhaps at an earlier stage. In our method of detecting the Ig class of the antibodies by precipitation with specific anti-Ig antiseras, we have chosen to consider a reduction of 2 dilutions in agglutination titre to indicate the presence of class-specific antibodies. This may be of borderline significance in some cases. On the other hand, it is unlikely that our precipitation technique removes the total Ig from the intestinal fluid or serum, so that the contribution of each Ig class may be underestimated. Bacterial agglutination techniques favour the detection of IgM and IgA antibodies rather than those of IgG class, so that we may have missed a significant IgG response.

The source of these intestinal antibodies is not known. The lack of correlation between serum and intestinal titres strongly suggests that the coproantibodies are not the result of leakage from the serum into the gut lumen. A lack of correlation between serum and gut antibodies has also been noted in the human studies of Girard and Kalbermatten (1970) and Lodinova et al (1970, 1973), in the studies of E. coli 0127 in mice by Kenny, Weinert, and Gray (1974), and in E. coli 0149 infections in the pig studied by Porter, Kenworthy, Holme, and Horsfield (1973). In contrast Fubara and Freter (1972) suggested that, in rabbits, a large proportion of intestinal antibodies were serum-derived.

No rise in serum antibodies was detected in six of our 15 patients. The explanation is not known. It may represent a difference in host response, or it may be the result of different properties of the infecting organism. Dupont, Formal, Hornick, Snyder, Libonati, Sheahan, LaBrec, and Kalas (1971) showed that some strains of enteropathogenic E. coli can penetrate mucosal barriers, in contrast to the majority of E. coli that remain within the gut lumen. The relationship of these properties to antibody responses requires further study.

We have measured agglutinating antibodies only. The protective effects of coproantibodies against E. coli are likely to be much more complex, involving antibacterial, antitoxic and anti-adherence properties (Smith and Linggood, 1971). Nevertheless it is of interest that we have recently studied three children with severe and protracted E. coli gastroenteritis in whom the coproantibody response was low. (Details will be published elsewhere.) Agglutinating coproantibodies may be important in the defence against enteropathogenic E. coli in human infants.

We are grateful to Professor Charlotte Anderson for her interest and encouragement, and to Professor P. G. H. Gell for laboratory facilities. Our consultant colleagues at Birmingham Children’s Hospital and East Birmingham Hospital kindly allowed us to study patients in their care. We thank Dr F. Bridgewater for help with bacterial identification, and Jean Fleming and Philip Turner for excellent technical help.

The work was supported by a grant to ASMcN and KBR from the Medical Research Council.
