From the Department of Medicine, Pathology and Dermatology, Mount Sinai School of Medicine, of the City University of New York, New York City, USA

SUMMARY A 38 year old female, with chronic uncontrolled coeliac disease, presented with the rare complication of cutaneous leucocytoclastic vasculitis. Detailed study failed to identify any cause for the vasculitis, other than the underlying coeliac disease. Haematuria and proteinuria with mesangial nephritis were also demonstrated on renal biopsy with electron microscopic study. It is speculated that exogenous or endogenous antigens permeated the abnormal small bowel mucosa leading to formation of circulating immune complexes. Subsequent tissue deposition of these complexes then resulted in vasculitis and nephritis. The skin lesions cleared completely after treatment with a strict gluten free diet.

Coeliac disease may give rise to a variety of dermatological manifestations.¹ Cutaneous vascular inflammation has been noted in some cases associated with cryoglobulinaemia.²⁻⁵ We report in detail the occurrence of leucocytoclastic vasculitis in a patient with established, poorly controlled coeliac disease.

Case report

A 38 year old Caucasian woman was admitted to the Mount Sinai Hospital, with a 20 year history of coeliac disease. Initially, institution of a gluten free diet resulted in complete clinical, biochemical, and histological remission. As her compliance waned, there was recurrence of her malabsorptive state for at least 10 years before the current hospital admission. Two months before admission, she noted the sudden development of purpuric, painful nodules over both lower extremities. These lesions coalesced to form indolent ulcers. Two months before the appearance of the skin lesions, she received a five day course of a sulphonamide for treatment of cystitis. No other medications or immunisations were given. She denied any drug allergy, fever, pruritis, joint pain, or Raynaud's phenomena. There was a 15 year history of insulin dependent diabetes, well controlled with isophane insulin suspension.

Incidentally, she had had documented microscopic haematuria and proteinuria for five years; intravenous pyelogram, cystoscopy, and renal function tests were normal.

Results of the general physical examination were normal. There was no lymphadenopathy or hepatosplenomegaly. Deep ulcerations were present on both lower extremities (Fig. 1). All pulses were normal.

Skin biopsy obtained from the ulcer edge was characteristic of leucocytoclastic vasculitis (Fig. 2). Immunofluorescent study of skin, with fluorescein conjugated monospecific antibody, revealed deposits of IgG, IgA, IgM, fibrin, and third complement component in the dermal blood vessels. In addition, a granular IgA staining at the dermal-epidermal junction, consistent with gluten enteropathy, was present.

Small intestinal mucosal biopsy showed complete loss of villi with plasma-cytic infiltration of the lamina propria. Contrast radiographs of the small bowel were consistent with sprue. There was no evidence of malignant lymphoma in the biopsy, radiographs, or abdominal CT scan and sonogram. Twenty-four hour faecal fat excretion was 12.2 g.

Urinalysis showed proteinuria and numerous red blood cells; no casts were seen. Twenty-four hour urine protein excretion was 300 mg, creatinine clearance 122 ml per minute. Urine and blood cultures were negative. Renal biopsy showed mesangial widening with increase in cells and matrix. Tubular basement membrane thickening consistent with diabetes was present, but glomerular basement

membranes were normal. Electron microscopy confirmed the histological changes and demonstrated mesangial electron dense deposits. There was no evidence of renal vasculitis.

The haemoglobin was 7.14 mmol/l (11.5 g/dl). Serum iron 5.9 $\mu\text{mol/l}$ (33 $\mu\text{g/dl}$), total iron binding capacity 38 $\mu\text{mol/l}$ (240 pg/ml), direct and indirect Coombs test, reticulocyte count, and serum haptoglobin were normal. White blood cell count was normal, as were platelets. Bone marrow aspirate and biopsy showed evidence of regeneration with no neoplasia. Erythrocyte sedimentation rate was 120 mm/hour. Routine blood chemistries were normal except for mild hyperglycaemia and serum albumen of 435 $\mu\text{mol/l}$ (3 g/dl). The following special tests were negative or normal: venereal disease research laboratory test, antinuclear antibody, latex fixation, anti-streptolysin O titre, serum thyroxine, serum cortisol, anti-thyroid, and anti-parietal cell antibodies. HBsag and anti-HBsag, total serum complement as well as third and fourth complement components, prothrombin time, partial thromboplastin time, fibrinogen, serum viscosity, urine Bence-Jones protein. There were no cryopro-

teins and serum SIA test was negative. Serum protein electrophoresis showed a diffuse increase in IgA to 8.1 g/l (810 mg/dl). Urine electrophoresis was normal. Radiograph of the chest was normal.

Institution of a strict gluten free diet over a four month period resulted in complete healing of the skin lesions. Her intestinal function improved at the same time.

Discussion

Clinical, biochemical, radiographic, and biopsy material are consistent with a diagnosis of coeliac disease.⁶⁻⁸ A variety of dermatological changes may occur during the course of coeliac disease, including desquamation or psoriatic dermatitis, pigmentation, purpura, hair and nail abnormalities, as well as the associated specific lesion of dermatitis herpetiformis.¹ Vasculitic skin lesions have been rarely encountered. Holdstock and Olesky² describe one case with a generalised dermatosis, biopsy of which showed a chronic inflammatory infiltrate adjacent to the basal layer of epidermis and around dermal capillaries. A more generalised vasculitis was presumed on the basis of a coexistent, unexplained seizure disorder. Booth³ briefly mentions three patients who developed a generalised erythematous rash, with extensive arteritis noted on skin biopsy. In these early reports of vasculitis²⁻³ extensive investigation was not described; the role of cryoglobulins, immune complexes, or other known causes of vasculitis cannot therefore be determined with certainty. Doe *et al.*⁴ describe four patients with mixed cryoglobulinaemia associated with cutaneous vasculitis; systemic vessels were involved in two. The cryoglobulins presumably acted as immune complexes; they had no activity against gluten fractions tested. Katz *et al.*⁵ report a patient and briefly refer to a petechial skin rash, which on biopsy was a vasculitis affecting small vessels of the dermis. There were no immunoglobulins or complement noted in the skin. Immune complexes were identified in the serum, as were antibodies to wheat fractions; no cryoproteins were present. In all cases the vasculitis occurred in the presence of severe, poorly controlled bowel disease. Several patients had pathological evidence of 'collagenous sprue', a condition particularly refractory to therapeutic intervention. Some consider that this is a specific entity,⁹ although the presence of collagen is not inconsistent with the diagnosis of coeliac disease.¹⁰⁻¹¹

Our patient had clinical and pathological abnormalities typical of leucocytoclastic vasculitis, with inflammatory disease confined to the skin. This vasculitis is characterised by involvement of small vessels, usually postcapillary venules. There is

infiltration of polymorphonuclear leucocytes with leucocytoclasia (nuclear debris), fibrinoid necrosis, and extravasation of erythrocytes. Although any organ may be involved, the skin is most common. The usual macroscopic appearance is palpable purpura; however, there may be urticaria, papules, nodules, vesicles, bullae, or the large ulcers seen in our patient. The lesions are at the same stage, suggesting episodic, rather than continuous, exposure to the aetiological factor.¹²

Leucocytoclastic vasculitis is, in most cases, mediated by immune complex deposition, the antigen being either exogenous or endogenous.¹³ The vasculitis may be an expression of a wide variety of distinct disorders.¹⁴⁻¹⁶ Extensive investigation failed to identify any of these associations in our case. There was exposure to a sulpha antibiotic, but the time interval between exposure to the drug and the onset of vasculitis makes this aetiology unlikely. The vascular inflammation would not be expected after removal of the precipitating antigen.¹⁴ We considered the possibility that her insulin therapy provided the offending antigen. However, change to pure pork insulin zinc suspension did not influence the clinical picture.

We speculate that the aetiology is related to the increased intestinal permeability of coeliac disease.¹⁶ As in other intestinal inflammatory disorders, exogenous antigens may permeate the damaged intestinal mucosa of coeliac disease in larger quantities than normal.¹⁷ This is reflected by significant serum antibody titres to a variety of exogenous proteins, such as milk and gluten fractions.¹⁸⁻¹⁹ Alternatively, release of endogenous antigens from damaged small bowel mucosa may occur and result in autoimmune sensitisation.²⁰ Humoral and cellular immunological activation and circulating immune complexes are well documented in coeliac disease.¹⁸⁻²² Perhaps immune complexes, originating from exogenous or endogenous antigens, are deposited in the skin, causing the leucocytoclastic vasculitis. The impaired phagocytic function of the reticuloendothelial system which occurs in coeliac disease would favour the circulation of such complexes.²³ Support for this concept is derived from the demonstration of cryoglobulins⁴ or immune complexes⁵ in the sera of a coeliac patient with vasculitis, and immune complex deposition in the skin of a patient with a lichen planus type rash.²⁴ Exogenous dietary antigens may be of prime importance, as reported cases with vasculitis occur among patients with uncontrolled coeliac disease, and, as in our case, may improve on a gluten free diet.⁵ The failure to identify endogenous intestinal brush border antigens in vasculitic lesions in sprue is also consistent with the role of dietary antigens.⁵ Auto-

immunity, however, cannot be eliminated with the meagre evidence available. All cases do not resolve on dietary control alone²⁴ and exogenous antigens have not been localised within immune complexes or vasculitic lesions.

The mesangial nephritis may be another manifestation of the coeliac disease in our case. Proteinuria, haematuria, and mesangial nephritis have been reported in dermatitis herpetiformis,^{25, 26} where bowel morphology may be identical with coeliac disease.²⁷ Moothy *et al.*²⁸ report a patient with dermatitis herpetiformis, gluten sensitive enteropathy, circulating immune complexes, and glomerulonephritis, primarily in the mesangial area. Katz *et al.*⁵ have since reported a patient with a similar immune complex glomerulonephritis and coeliac disease without dermatitis herpetiformis. The electron dense mesangial deposits seen in the renal biopsy of our case are consistent with this immune complex aetiology and may provide a link between our patient's coeliac disease, vasculitis, and renal abnormality.

Treatment of leucocytoclastic vasculitis generally has been frustrating. There is little evidence that any of the known methods of treatment, including corticosteroids, significantly alter the course of the disease.¹² Holdstock and Oleesky² noted improvement of the dermatosis in their case associated with coeliac disease, but they had at the same time instituted a gluten free diet. Dietary therapy alone has been successful⁶ and, in our patient, has allowed remarkable resolution of the vasculitic ulcers. The patient reported should remind us of the possible protean nature of the complications of coeliac disease and stress the importance of strict dietary control.
