SUMMARY Histochemical studies have shown a relative depletion of colonic sulphated mucins (sulphomucins) in active ulcerative colitis. One possible explanation for this could be desulphation by bacterial sulphatases. Studies have therefore been done to determine whether normal faeces contain sulphatase and if so to determine whether this activity is increased in ulcerative colitis. Using a fluorimetric assay considerable sulphatase activity (>0.3 IU/g pellet weight) was found in bacteria free filtrates of the homogenates of nine of 17 faecal samples from healthy controls. This sulphatase activity had an alkaline pH optimum (pH 8.5–9.5). A similar range of faecal sulphatase activity with a similar pH optimum was found in samples from patients with ulcerative colitis (n=39) and Crohn’s disease (n=17) and there was no correlation with disease activity in either disease. This faecal sulphatase activity may be involved in the degradation of colonic mucus and merits further study but these findings do not explain the relative depletion of colonic mucosal sulphomucins in ulcerative colitis.

In health a large proportion of the human colonic mucus is sulphated but in active ulcerative colitis and Crohn’s disease histochemical studies have shown a relative depletion of colonic sulphomucins. The normal colonic flora contains bacteria which produce glycosidases capable of degrading colonic mucins but it is not known whether sulphatase producing bacteria are also present. It is quite likely that they are as rat faeces have been shown to contain sulphatase activity which is abolished by prior antibiotic treatment and which seems to be produced mainly by a lactobacillus.

There are several reasons why sulphatase production by faecal organisms might be important in the pathogenesis of colonic disease. If the sulphatases were capable of desulphating colonic mucus they would alter its charge and hence its physical properties and also probably increase its susceptibility to further degradation by bacterial glycosidases. Sulphatases might also activate toxins such as lithocholic acid which are detoxified by sulphation. Assays of faecal sulphatase activity have therefore been undertaken on samples obtained from patients with inflammatory bowel disease and from healthy controls.

Methods

SUBJECTS

A faecal sample was obtained from each of 17 healthy control subjects (university students) and 39 samples were obtained from 32 patients with ulcerative colitis and 17 samples from 14 patients with Crohn’s disease. Of the ulcerative colitis samples seven were from patients in remission, six from patients with mild disease, 15 moderate and 11 severe disease as defined by clinical criteria. Of the Crohn’s disease samples four were from patients in remission, four from patients with mild disease, four moderate, and five severe disease judged by similar clinical criteria. Nine of the Crohn’s disease patients had ileo-colonic disease, four had colonic disease only and one had ileal disease only. Only six of the patients with ulcerative colitis and three of the patients with Crohn’s disease were hospital inpatients at the time of the study. No patients had received antibiotics within the previous month but 21 of the ulcerative colitis samples and three of the Crohn’s disease samples were collected from patients receiving sulphasalazine. The faecal samples were collected in 20 ml sterile universal containers and frozen at −20°C within four hours of voiding. Preliminary studies have shown that faecal sulphatase is stable at −20°C for at least four weeks.
ENZYME ASSAYS

Three aliquots, each approximately 0.5 g were taken from each faecal sample, thawed and homogenised in 30 ml 0.2M Tris acetate buffer using a loose fitting glass homogeniser. Assays were performed on each sample using Tris acetate buffer at pH's 5.5, 6.5, 7.5 and 8.5. The faecal homogenates were then centrifuged at 15000 g for 30 minutes at 5°C. The resulting pellets were weighed and the supernatants filtered through a series of prefilters culminating in a 0.22 μm pore diameter filter (Millipore, UK) to obtain a bacteria free filtrate. Two aliquots of each filtrate were assayed fluorimetrically11 for sulphatase activity using 0.02 mM 4-methyl umbelliferyl sulphate (Sigma) as substrate. Assays were performed over 10 minutes at 37°C, inhibited by the addition of 0.1 ml 1.33 M glycine buffer pH 10.7 and fluorescence estimated immediately using an Amino-Bowman spectrophotometer at 365 nm extinction, 450 nm absorbance. For each sample the results obtained at each pH represent the mean of six readings. Mean variation between aliquots from the same faecal sample was 4%. Enzyme activity was expressed as μmol methyl umbelliferyl released/minute (IU)/g pellet weight. The results were expressed in this way to avoid misleading alterations in enzyme concentration that might otherwise result from a dilutional effect of diarrhoea.

Results

Sulphatase activity >0.3 IU/g pellet weight was detectable at pH 8.5 in nine of 17 normal faecal samples, 12 of 39 ulcerative colitis samples and six of 17 Crohn's disease samples. In all samples tested from control subjects and patients with ulcerative colitis or Crohn's disease the faecal sulphatase had an alkaline pH optimum (pH 8.5-9.5) (Fig. 1). There was no significant difference overall between faecal sulphatase activity in samples obtained from the normal controls and the samples obtained from patients with ulcerative colitis or Crohn's disease. (Fig. 2, Table). Although several high faecal sulphatase values were recorded in patients with active ulcerative colitis there was no obvious trend towards increased faecal sulphatase in more active disease in either ulcerative colitis or Crohn's disease. Little or no sulphatase activity was detectable in any of the samples tested at pH 5-5 or 6-5 (Table 1). In ulcerative colitis there was no significant difference in faecal sulphatase activity between those patients receiving sulphasalazine (0.75±1.97 IU/g at pH 8.5, mean±SD) and those not (1.16±2.19 IU/g at pH 8.5, mean±SD).

Discussion

This study shows that sulphatase activity is commonly present in normal human faeces. The sulphatase has an alkaline pH optimum (between pH 8.5 and pH 9.5) which makes it probable that it is bacterial in origin, like the rat faecal sulphatase previously reported,6 as the lysosomal sulphatase

arylsulphatase A and B have acidic pH optima as do human N-acetyl glucosamine 6-sulphate sulphatase and N-acetyl galactosamine 6-sulphate sulphatase while the microsomal arylsulphatase C is insoluble and seldom detected in body fluids. A large number of bacteria are known to produce sulphatases particularly the Enterobacteriaceae including strains of Klebsiella, Escherichia, Salmonella and Citrobacter and most of these sulphatases have neutral or alkaline pH optima.

Sulphatases capable of acting on the 4-me umbelliferyl-sulphate substrate used in this study may not necessarily be capable of desulphating colonic mucus but it is probable that some at least are capable of this as histochemical studies show that the rectal mucus becomes desulphated if rectal biopsies are incubated in faecal extracts prepared in a similar way to those used in this study. Although the pH optimum of the total faecal sulphatase activity is higher than normal or colitic faecal pH (5.5–6.5 approximately) these histochemical studies showed that faecal extracts are able to desulphate colonic mucus at pH 5.5. It is also known that some bacteria produce sulphatases which desulphate lithocholate sulphate liberating lithocholic acid which is potentially toxic to colonic mucosa.

In this study similar levels of sulphatase activity were found in faeces from normal controls and from patients with ulcerative colitis or Crohn’s disease although a small number of samples from patients with active ulcerative colitis contained considerably greater sulphatase activity. The reduced sulphation of colonic mucus shown histochemically in ulcerative colitis in the absence of increased faecal sulphatase activity could be because of either increased susceptibility of the mucus to desulphation by bacteria or of decreased sulphation during mucus synthesis.

The presence in faeces of sulphatase activity which has the potential to desulphate mucus and toxins normally inactivated by sulphation could be pathogenically important in colonic disease.

This work was carried out with the help of a grant from the Birmingham Central District Endowment Fund.
