Involvement of alpha-1 and alpha-2 adrenoceptors in the postlaparotomy intestinal motor disturbances in the rat

A SAGRADA, M J FARGEAS, AND L BUENO

From the Department of Pharmacology, INRA, Toulouse, France

SUMMARY The effects of phentolamine, yohimbine and prazosin on laparotomy induced intestinal motor disturbances were studied in anaesthetised fasted rats previously equipped with electrodes, chronically implanted on the duodenum and jejunum. During continuous recording of inter-digestive myoelectric activity, laparotomy under thiopental anaesthesia (Nesdonal 40 mg/kg ip) induced a primary phase of total inhibition of spiking activity lasting 26.1 ± 1.3 min (mean $\pm$ SE) followed by a period of disorganised activity, the first propagated migrating myoelectric complex (MMC) occurring 71.4 ± 7.9 min after laparotomy. Phentolamine (3 mg/kg), or yohimbine (1 mg/kg) given im before laparotomy decreased by 48 and 49%, respectively, the duration of postsurgical inhibition, with a normal MMC pattern occurring immediately after. In contrast, there was only a shortening of the postlaparotomy initial inhibition of spiking activity after im prazosin (100 μ g/kg), with a late (50-60 min) recovery of the MMC pattern. These results suggest that the initial inhibition of intestinal motility induced by laparotomy may involve alpha-1 and alpha-2 adrenoceptors, while the disruption of the MMC pattern is mainly caused by the activation of alpha-2 receptors.

A transitory suppression of gastrointestinal motility (ileus) is a common complication of abdominal surgery and trauma. Although stomach and colon are generally believed to be most affected,¹ a period of postsurgical paresis of small bowel has been clearly shown in rats² and dogs.³ In these species a clearcut suppression of spiking activity after laparotomy has been shown: the recovery of myoelectric activity occurs as incoordinated motility at first, followed by a progressive restoration of the organised fasted pattern – that is, the migrating myoelectric complex (MMC), which assumes the normal propulsive and secretory function. In both species, prolonged disruption of myoelectric activity caused by exposure of the bowel to air, intestine handling or related to the nature of surgery was observed.^{2,3} Moreover, the

propulsion of a marker along the small bowel of the rat is inhibited by laparotomy.^{4,5}

In man, although postoperative radiological investigations attribute normal propulsive activity to small intestine,¹ a disturbance in the coordination of myoelectric activity in the early postoperative period has been shown, with disruption of the basic electrical rhythm (slow waves) and irregular occurrence of spiking activity.⁶

Hyperactivity of the sympathetic nervous system plays a prominent role in the genesis of this post-surgical event:⁷ it is prevented in rats by chemical and surgical sympathectomy,⁴ but not by adrenalectomy.⁵ Sympathetic hyperactivity also seems to be basic to gastric⁸ and colonic⁹ ileus, if produced by peritoneal irritation, and to act synergistically with vagal non-adrenergic inhibitory fibres in decreasing gastric motility after laparotomy.¹⁰ The roles of alpha-2 receptors located in the gut and involved in the

regulation of gastrointestinal secretion and motility are widely documented;¹¹⁻¹⁴ on the other hand, the role of alpha-1 receptors in this field is less clear. The present study was undertaken in order to clarify the role played by alpha-1 and alpha-2 receptors in the genesis of postsurgical ileus in the rat.

Methods

ANIMALS

Male Wistar rats, weighing 250–300 g were used; they were housed in individual cages, fed on UAR pellet diet and given water *ad libitum*. Under halothane (Fluothane) anaesthesia, Nichrome wire electrodes (0.08 mm diameter) were implanted into the muscular layers of the small bowel, according to a previously described technique.¹⁵ The groups of electrodes were placed respectively on the duodenum at approximately 10 cm from the pylorus, and on the jejunum at approximately 20 and 30 cm from the pylorus.

EXPERIMENTAL PROCEDURES

Starting five to six days after surgery, the electrical activity of small bowel was recorded by means of an electroencephalograph (Reega Minihuit, Alvar; time constant 0.1 sec; paper speed 6 mm/min). In addition an integrated record of spiking activity was obtained by summation of the electrical activity for consecutive 20 second periods using a linear integrator circuit¹⁶ connected to a potentiometric recorder (JJ Lloyd CR 503; paper speed 6 cm/h).

Experiments were carried out at three day intervals on each rat. The animals were fasted overnight and water was allowed *ad libitum*. After two hours of control recording of the interdigestive cyclic activity of small bowel, anaesthesia was induced by intraperitoneal injection of 40 mg/kg thiopental (Nesdonal). A 2 cm paramedian laparotomy was done in the umbilical region, according to the following time schedule: incision of the skin 10 minutes after barbiturate administration (stage 1); incision of muscle layers and peritoneum during the occurrence, at the upper jejunal site, of the third MMC after thiopental injection (stage 2), followed by immediate closing of the laparotomic wound. Drugs to be tested (or vehicles) were injected by intramuscular route during the occurrence, at the upper jejunal site, of the second MMC after thiopental administration – that is, about 15–18 minutes before performing stage 2 of surgery.

The drugs were dissolved in 0.5 ml vehicle and injected in the following doses: phentolamine HCl: 3 mg/kg; yohimbine HCl: 1 mg/kg; prazosin HCl: 100 µg/kg (the doses refer to the compounds as salts). Phentolamine was dissolved in distilled water, yohimbine and prazosin were dissolved in a 10%

dimethylsulphoxide/water solution. Control animals received either 0.5 ml of the dimethylsulphoxide/water solution intramuscularly (n=4) or 0.5 ml of distilled water (n=4). Because no significant difference between the two control groups was found for each of the parameters considered (ANOVA), one control group was made by pooling the data.

ANALYSIS OF DATA

The following variables were considered: (a) time of complete inhibition of myoelectric activity: from stage 2 of surgery to the appearance of the first spiking activity at one of the recording sites; (b) time of disruption of the MMC pattern: from stage 2 to the appearance of the first MMC propagated over at least two recording sites; (c) MMC period: time between the beginning of regular spiking activity of successive complexes at the upper jejunal site. For each rat, basal MMC period is the mean of three successive periods before thiopental administration. In order to compare presurgical and postsurgical mean MMC periods, the mean of the periods between thiopental injection and stage 2 and the mean of the first three periods after laparotomy were calculated for each experiment.

STATISTICAL ANALYSIS

Data were analysed using Student's *t* test for paired (variable c) or unpaired data (variables a and b).

Results

The small bowel motor profile in fasted rats was characterised by the occurrence of migrating myoelectric complexes having a mean period, at the upper jejunal site, of 13.9 ± 0.7 min (n=8), and comprising two phases of irregular and regular spiking activity, as previously described.¹⁶ Thiopental did not modify the cyclic motor profile; however, it induced lengthening of the MMC period by $15 \pm 2\%$ ($p < 0.05$), and, in some experiments, shortening of the phase of irregular spiking activity (n=2). Finally, a transient inhibition or disruption of the organised myoelectric activity just after the injection, rapidly followed by recovery of the normal motility pattern, was sometimes observed (n=6).

EFFECT OF LAPAROTOMY

Paramedian incision of the skin did not significantly alter regular development and migration of the ongoing myoelectric complex (Figs 1, 2). In contrast, incision of muscle layers and peritoneum produced the instantaneous interruption of the ongoing complex (Figs 1, 2) and the complete inhibition of any spiking activity for 26.1 ± 1.3 min. Recovery of an irregular spiking activity was then detectable at one

Fig. 1 Effect of laparotomy (S2) under thiopental anaesthesia on the myoelectric activity of duodenojejenum at 10 (D), 20 (J1) and 30 (J2) cm from the pylorus (direct record). Upper traces: control laparotomy. Lower traces: laparotomy in yohimbine-treated rats (1 mg/kg im). S1 indicates skin incision.

of the recording sites. The mean interval between stage 2 of the surgery and the reappearance of a myoelectric complex propagated over at least two recording sites was longer, with a mean duration of 71.4 ± 7.9 min. At the recovery of the organised pattern, the MMC period was lengthened compared with the presurgical state ($p < 0.01$) (Table).

EFFECT OF DRUGS

Phentolamine

In animals pretreated with phentolamine, laparotomy immediately suppressed intestinal myoelectric activity; the duration of total inhibition of spiking activity was less compared with controls ($p < 0.01$), as disorganised bursts of spikes reappeared 13.5 ± 0.6 min after laparotomy (Table). The MMC pattern recovered after 20.7 ± 7.0 min ($p < 0.05$), but the MMC period was longer than presurgically ($p < 0.05$) (Table).

Yohimbine

Pretreatment with yohimbine did not prevent the interruption of the MMC by laparotomy (Fig. 1); however, the suppression of myoelectric activity lasted 13.2 ± 1.9 min, and the first MMC occurred 13.6 ± 2.2 min after stage 2 of surgery (Fig. 1, 2). The recovery was faster than in controls ($p < 0.01$) and the MMC pattern was immediately organised; there was little or no effect of laparotomy on the MMC period ($p > 0.7$) (Table).

Fig. 2 Effect of laparotomy (S2) under thiopental anaesthesia on the myoelectric activity of duodenojejenum at 10 (D) and 20 (J) cm from the pylorus (integrated record). Upper traces: control laparotomy. Lower traces: laparotomy in yohimbine treated rats (1 mg/kg im). S1 indicates skin incision.

Prazosin

Prazosin reduced the duration of laparotomy induced ileus ($p < 0.01$), as with phentolamine or yohimbine; however, the reappearance of a propagated MMC was similar to controls ($p > 0.4$), and the MMC profile showed a quite irregular frequency during several hours, with alternating periods of organised and disorganised spiking activity (Table).

Discussion

The present work confirms the inhibitory effect of laparotomy on the myoelectric activity of rat small bowel,² and the participation of adrenergic pathways in the genesis of this pathology.^{2,4,7} Furthermore, it establishes that mainly alpha-2 adrenoceptors are involved. As previous works showed, thiopental anaesthesia leaves the interdigestive myoelectric pattern in rat substantially unchanged;² transient alterations sometimes observed in our experiments were probably caused by the stress of restraint and of the ip injection, and in these cases we waited

Table Influence of adrenoceptor blockers on the inhibition of duodenojejunal myoelectric activity induced by laparotomy in rats

	Time (min) of myoelectric activity inhibition	Time (min) of MMC pattern disruption	Mean MMC period (min)	
			Presurgically	Postsurgically
Controls (n=8)	26.1 ± 1.3	71.4 ± 7.9	16.4 ± 1.0	$30.8 \pm 3.8 \ddagger$
Phentolamine (im) (n=4)	$13.5 \pm 0.6 \dagger$	$20.7 \pm 7.0^*$	15.5 ± 1.4	$21.7 \pm 2.3 \S$
Yohimbine (im) (n=5)	$13.2 \pm 1.9 \dagger$	$13.6 \pm 2.2 \dagger$	17.1 ± 2.4	17.5 ± 3.0
Prazosin (im) (n=5)	$13.4 \pm 2.2 \dagger$	52.4 ± 17.0	15.2 ± 1.1	Not calculated

Values are means $\pm$ SE; difference v controls: * = $p < 0.05$; $\dagger$ = $p < 0.01$. Difference v presurgical period: $\ddagger$ = $p < 0.05$; $\S$ = $p < 0.01$.

for the recovery of the normal pattern before starting surgery. Incision of abdominal muscle layers and peritoneum abruptly interrupts intestinal motility,^{2,3} and this effect is consistently prevented by partial destruction of the spinal cord^{2,17} or by splanchnicectomy.^{2,3,18} These data suggest the existence of an inhibitory reflex activated by laparotomy, involving the spinal cord and the splanchnic nerves as the main efferent pathway. In support of this proposition, increased synthesis and release of gut noradrenaline occurs 12 hours after abdominal surgery in rats.¹⁹ Moreover, adrenalectomy does not affect the postoperative slowing of rat small intestinal propulsion measured 12 hours after surgery.⁵

As previously shown, two phases occur in the postlaparotomy ileus: a total suppression of myoelectric activity, followed by a period of unorganised spiking activity.² In our experiments the first period was shortened by phentolamine, yohimbine, or prazosin pretreatment, indicating that both α -1 and α -2 receptors may mediate inhibitory stimuli affecting small bowel motor activity postoperatively. The most important finding, however, concerns the faster recovery of the MMC pattern with phentolamine or, notably yohimbine. This early restoration of the MMC, not seen with prazosin, supports the hypothesis that α -2 receptors play a major role in the postlaparotomy disruption of the MMC pattern. α -2 receptors can mediate inhibition of intestinal motility.^{12,20,21} Activation of these adrenoceptors, thought to be presynaptically located,²² can inhibit acetylcholine output in guinea pig ileum,^{23,24} and a similar mechanism has also been proposed for dog jejunum³⁰ and rabbit intestine.²⁵ In rat small intestine, acetylcholine may not be the main excitatory neurotransmitter;²⁶ nevertheless, because clonidine²¹ (and paradoxically prazosin)²⁷ reduces small bowel propulsive activity in rats, laparotomy induced ileus may be caused by the postoperatively increased release of gut noradrenaline, which, acting on presynaptic α -2 receptors, inhibits the release of a neurotransmitter important for the regularly cycling MMC. α -2 receptors may also be important in regulating rat colonic motor activity, as inhibition of motility by nociceptive peritoneal stimuli was counteracted by phentolamine or yohimbine.⁹

Because there is a relationship between the MMC pattern and propulsion of contents in rat,^{15,28} peripheral blockade of α -2 adrenoceptors would be expected to result in a faster recovery of normal intestinal motility.

None of the drugs used prevented the instantaneous suppression of spiking activity caused by musculoperitoneal incision; other nervous pathways may therefore contribute to postlaparotomy ileus.
