Failure of ornithine decarboxylase inhibition to alter small intestinal epithelial repair after transient segmental ischaemia

C GUZMAN, R J MACLEOD, AND J R HAMILTON

From the Department of Paediatrics, University of Toronto and The Research Institute, The Hospital for Sick Children, Toronto, Ontario, Canada

SUMMARY To evaluate the roles of ornithine decarboxylase (ODC) and polyamines in the regulation of epithelial repair, rabbit mid-small intestine after transient ischaemic villus injury in the presence and absence of DL-difluoromethylornithine (DFMO), an irreversible inhibitor of ODC was studied. Rabbits received 2% (w/v) DFMO in drinking water for two days before undergoing a sham laparotomy, or a 90 minute mesenteric vascular occlusion of 20 cm of mid-intestine. DFMO fed and control rabbits were studied four, 24, 72, or 120 hours after this ischaemic intestinal injury. In controls, ischaemic injury caused shortened villi at four hours (p<0.01), diminished mucosal sucrase and alkaline phosphatase activities at 24 hours (p<0.05), but raised ODC (p<0.001) and thymidine kinase (p<0.01) activities at four hours with recovery by 72 hours. DFMO treatment significantly reduced ODC activity at all stages of the experiment and significantly inhibited the rise in activity observed after injury (p<0.01). Mucosal concentrations of the polyamines, spermidine and spermine, were similar in the sham operated groups; four hours and 24 hours after ischaemia, they increased in the DFMO animals (p<0.01) but fell (p<0.05) in those that did not receive DFMO. After ischaemic injury, DFMO treatment inhibited ODC but failed to influence recovery of villus structure or enzyme activities in the small intestine. We conclude that ODC and the polyamines, spermidine and spermine, are not key regulators of small intestinal repair after transient ischaemia.

Recent reports have suggested that polyamines are involved in the regulation of the proliferation of cells, including those in the small intestinal epithelium.1-3 A putative rate limiting enzyme in polyamine synthesis is ornithine decarboxylase (ODC: EC4-1-1-17),4,5 for which DL-difluoromethylornithine (DFMO) is a specific enzyme activated inhibitor.6 To evaluate the importance of polyamines in regulating repair of the small intestinal muscosa after injury, DFMO was given to young rabbits. Then, after inducing transient ischaemic damage in a segment of small intestine, we measured the effect of DFMO on structural and functional recovery from this injury.

Methods

ANIMALS
Sixty New Zealand white rabbits, each weighing approximately 2.5 kg were allowed to acclimate to our animal facilities for one week before they were studied. Rabbits were housed in individual cages; they had free access to water and conventional rabbit chow* throughout the study. Thirty rabbits were assigned at random to receive DFMO (MDL 71782, Merrell Dow Research Institute, Cincinnati, Ohio) in their drinking water as a 2% (w/v) solution for two days before they were subjected to intestinal injury or to a sham laparotomy. Preliminary dose response data of DFMO feeding for two days had shown maximal inhibition of small intestinal mucosal ODC activity at a concentration of DFMO in drinking water of 2%; ornithine decarboxylase was inhibited
87, 96, 96, and 98% after ingestion of DFMO at concentrations of 0.5, 1.0, 1.5, and 2% w/v respectively. The control treatment group received no additive to their drinking water. Animals from the DFMO treatment group and the control group underwent mesenteric arterial clamping in which the blood supply to a 20 cm segment of mid-intestine was occluded for 90 minutes under general anaesthesia, using techniques similar to those described for the rat. In an earlier study, we determined that periods of occlusion exceeding 90 minutes caused irreversible necrosis while shorter periods failed to produce significant mucosal injury. Mid-intestine was defined as a 20 cm segment taken at the midpoint between the ligament of Treitz and the ileo-cecal valve. Serosal sutures were placed at the proximal and distal ends of this occluded segment for later identification of the injured segment. Sham laparotomy procedure consisted of an abdominal incision and manipulation, but no occlusion of mesenteric vessels. All animals received DFMO-free water after surgery.

Animals were killed four, 24, 72, or 120 hours after operation by parenteral Na pentobarbitol and segments of intestine were taken quickly for microscopic and biochemical studies. For light microscopic measurements, 2 cm sections were fixed in Bouin’s solution and stained with haematoxylin-eosin. We measured a minimum of 10 crypt villus units in properly oriented sections, using a calibrated micrometer eyepiece. Suckase activity was measured in whole mucosal homogenates by the method of Dahlqvist, alkaline phosphatase by the method of Kelly and Hamilton, and thymidine kinase by a modification of the method of Klemperer and Haynes.

We measured ornithine decarboxylase by a modification of the technique of Kudlow et al. Appropriately segments of small intestine after removal were quickly flushed with ice cold saline, and opened. The mucosa was scraped off with a glass slide and homogenised 1:10 (w/v) in ice cold 50 mM Tris-Cl, 5 mM diithiothreitol (DTT), 0.1 mM Na EDTA, pH 7.1, then quick-frozen in an acetone dry ice bath and stored for up to three days at -70°C. After thawing, the homogenate was sonicated for 15 seconds at 100W and then centrifuged at 27,000 g for 20 minutes. Aliquots of the supernatant were added to a reaction mixture containing 0.5 µCi DL-(1-14C) ornithine (61 mCi/mmol), 50 mM Tris Cl, 5 mM diithiothreitol, 0.25 mM ornithine, and 0.25 mM pyridoxyl-5-phosphate, pH 7.1, and incubated in stoppered tubes at 37°C for one hour in a Dubnoff metabolic incubator. The reaction was stopped by adding 1 ml of 10% (w/v) trichloroacetic acid (TCA) and incubated at 37°C for an additional hour. The liberated 14CO2 was trapped on an impaled filter disc (BD sensitivity disc, Becton-Dickson) that had been spotted with 25 µl of a 50% solution of Protosol (New England Nuclear) in toluene. Blank reactions were stopped before incubation by addition of 1 ml of 10% TCA and treated as above. The filter discs were transferred to 10 ml Aquasol-2 (New England Nuclear), allowed to sit for 12 hours to quench chemiluminescence, and then counted in a scintillation counter. Counts recovered from the reaction blank were subtracted from the mean of the counts recovered from the sample. Under these conditions the assay was linear with time and protein concentration. In preliminary experiments we had compared the filter disc method with the use of suspended wells and found the discs 30% more efficient in trapping 14CO2 over the same time course.

Protein was measured in aliquots of supernatant after TCA precipitation. Precipitates were solubilised in 1 N NaOH. One unit of enzyme activity was defined as one nmol 14CO2/h and results expressed as mU/mg protein. Activity was measured within three days of sampling as preliminary experiments showed a monotonic decline of ODC activity recovered from small intestinal mucosa stored at -70°C for longer than 3 days. Although the in vivo half-life of ornithine decarboxylase is very short recent work using partially purified ornithine decarboxylase has confirmed that in vitro activity loss of ornithine decarboxylase was caused by oxidative inactivation which was prevented in the presence of dithiothreitol. Our in vitro incubation contained sufficient dithiothreitol to prevent oxidative inactivation of the enzyme. Furthermore, in preliminary experiments we found unacceptable intra and inter batch assay variability; consistent with other reports this variability was completely eliminated by first evaporating the labelled ornithine substrate to dryness in a Rotary-Mix evaporator (Buchler Instruments) at 55°C and dissolving the residue with 0.01 N HCl which was then stored at 4°C until it was used. Using this evaporated ornithine, killed (non enzymic) control incubations gave 57 ± 16 dpm (n = 25) with the usual final specific radioactivity used in the assay (0.5 µCi/20 µmol DL-ornithine).

We used the technique of Wagner et al. to measure spermidine and spermine. Putrescine was not measured. Mucosal homogenate was mixed with equal volumes of 0.4 M perchloric acid, centrifuged at 3000 g for 15 minutes, and the supernatant filtered through Millipore filters (0.22 µm). Aliquots of 25 µl of the filtered acid extract were injected on the column of an HPLC system. For final calculation the tracings were cut off, weighed, and read, from standard curves of spermidine and spermine. Results are expressed in nmol/mg of extracted protein.
Ornithine decarboxylase inhibition

We obtained \(^{14}\)C-ornithine from Amersham (Montreal, Quebec), \(^{14}\)C-thymidine from New England Nuclear (Boston, MA), and the remaining reagents from Sigma Chemical (St Louis, MO).

**Statistical Analysis**

All data were subjected to analysis of variance, and intergroup differences (sham operated, ischaemic injury) were analysed by a one-way analysis of the least significant difference method. Calculations were performed with a Hewlett-Packard 85 micro-computer, and significance was considered to be \(p<0.05\).

**Results**

**Light Microscopy**

Small intestinal mucosal measurements in DFMO treated and control groups before and after ischaemic injury are summarised in Figure 1. In sham operated animals, DFMO treatment had no impact on total crypt villus length. Four hours after ischaemia, mean villus length was significantly reduced compared with shams in both control (630.2 ± 39.1 μm vs 316.5 ± 40.4 μm, \(p<0.01\)) and in the DFMO treated (619.2 ± 37.9 μm vs 325.8 ± 25.9 μm, \(p<0.01\)) groups. Twenty four hours after ischaemia in non-DFMO fed controls, mean villus length, although 18% less, was not significantly different from sham operated controls (\(p=0.07\)). There were no significant differences in mean villus length between the two groups, at either four hours or 24 hours after ischaemia. The crypts were significantly increased in depth at 24 hours after ischaemia in non-DFMO treated controls (214.5 ± 16.1 μm vs 140.6 ± 13.3 μm, \(p<0.05\)) and in the DFMO-treated rabbits (169.9 ± 25.1 μm vs 119.6 ± 5.7 μm, \(p<0.05\)). There was no significant difference in the crypt depth between the two treatment groups.

**Mucosal Enzymes**

In sham operated animals, DFMO treatment did not affect the specific activities of mucosal sucrase, alkaline phosphatase, or thymidine kinase (Table 1). In non-DFMO fed rabbits, sucrase specific activity was significantly decreased from preinjury levels, 24 hours after ischaemia (\(p<0.05\)). At 120 hours, although the mean concentration of sucrase was 26% less than for sham-operated controls, it was not significantly different from those controls (\(p=0.25\)). In the DFMO treated group, sucrase specific activity was significantly decreased at both four hours (\(p<0.05\)) and 24 hours (\(p<0.01\)) in comparison with its sham operated control. At 72 hours the activity had returned to its sham operated value and was not significantly different from the control group.

Alkaline phosphatase specific activity was significantly decreased at 24 hours (\(p<0.05\)) in comparison with the respective sham operated control in both groups. In the non-DFMO fed group at 72 hours, the activity was greater (\(p<0.05\)) than in shams; while in the DFMO group the activity was significantly raised (\(p<0.05\)) above sham operated levels at 120 hours after ischaemia. In non-DFMO fed rabbits, four hours after ischaemia, thymidine kinase activity was raised (\(p<0.01\)). Thymidine kinase was raised (\(p<0.05\)) 24 hours after ischaemia in the DFMO fed rabbits.

Mucosal ornithine decarboxylase (ODC) specific activities in each study group are compared in Figure 2. As expected, DFMO treatment inhibited the enzyme in sham operated rabbits (0.3 ± 0.1 mU/mg vs 3.3 ± 0.9 mU/mg, \(p<0.01\)). In non-DFMO treated rabbits, four hours after ischaemia injury, ODC specific activity was raised 15× compared with the sham operated group (50.0 ± 12.3 mU/mg vs 3.3 ± 0.9 mU/mg, \(p<0.001\)) but by 24 hours it had returned to normal. The activity of ornithine decarboxylase increased also in DFMO fed rabbits four hours after ischaemic injury (1–8 (0.5) mU/mg vs 0.3 (0.1)
mU/mg, p<0.05) remained raised (p<0.01) above sham operated levels at 24 hours and 72 hours, but returned to normal at 120 hours. In comparison with non-DFMO fed rabbits, however, ornithine decarboxylase activity was less at four hours (p<0.01), 24 hours (p<0.05), 72 hours (p<0.005), and at 120 hours (p<0.005).

**MUCOSAL POLYAMINES**

In jejunal mucosal homogenates from sham operated rabbits, spermine and spermidine concentrations were not significantly affected by DFMO (Table 2). The levels of spermidine decreased (p<0.05) at four hours and 24 hours after ischaemia in non-DFMO fed rabbits. In the DFMO fed group, the concentration of spermidine did not change compared with sham operated controls at four hours but it was increased at 24 hours (p<0.05). At four hours and 24 hours spermidine concentrations were greater (p<0.05) in comparison to the non-DFMO fed groups. The concentration of spermine in the non-DFMO fed group at both four hours and 24 hours after ischaemia was significantly less (p<0.01) in comparison to the sham operated control. In the DFMO treated group, spermine concentrations were decreased (p<0.05) at four hours but significantly increased (p<0.01) at 24 hours after ischaemic injury. At both four hours (p<0.01) and 24 hours (p<0.001) mucosal concen-

trations of spermine were greater in DFMO treated groups than in non-DFMO treated group.

Discussion

In the current experiments 90 minute segmental occlusion of small intestinal vascular flow caused transient structural and functional damage in the villus compartment of the occluded segment, associated with an apparent increased proliferation of the epithelium in the crypts. Previous studies using rabbits in our laboratory, and in rats, yielded similar observations. Villus epithelial cell damage was confirmed in the current experiments by our findings or altered villus morphometry and diminished mucosal sucrase and alkaline phosphate activity. The proliferative response in crypts to this villus cell injury is suggested by the observed increase in mucosal thymidine kinase activity, an enzyme known to be enriched in populations of rapidly dividing cells, and by the subsequent crypt elongation.

In non-DFMO treated control animals, immediately after experimental ischaemic injury, a 15-fold increase of ornithine decarboxylase specific activity in the mucosa of the injured segment was seen and a subsequent return to basal levels as the proliferative response subsided. In other experimental models in which crypt cell proliferation has been induced, a similar transient ornithine decarboxylase response has been observed. Indeed, after jejunectomy in the rat ornithine decarboxylase increased 170-fold with subsequent increases in putrescine, spermidine, and spermine. Such data in proliferating intestinal epithelia have supported the concept that polyamines and the rate limiting enzyme in the biosynthetic pathway of polyamines, ornithine decarboxylase are involved in the control of intestinal epithelial renewal. In this study DFMO treatment inhibited the transient marked increase in intestinal mucosal ornithine decarboxylase specific activity after injury by 96%, consistent with other data showing, after DFMO feeding, 65% to 98% inhibition of ornithine decarboxylase increases. In spite of near complete inhibition of ornithine decarboxylase in our DFMO-fed rabbits, the concentrations of spermine and spermidine in the small intestine did not diminish as expected but increased after ischaemic injury.

Our data do not support the concept that ornithine decarboxylase is an important regulator of small intestinal epithelial repair in the rabbit. The rise of spermine and spermidine concentrations in the mucosa of DFMO treated rabbits suggests that under our experimental conditions, polyamine uptake by intestinal mucosal cells may have increased. In vitro studies have shown that DFMO and other inhibitors of polyamine synthesis can enhance tissue uptake rates of putrescine or spermidine. The failure of ischaemic injury to influence tissue spermine and spermidine concentrations in the presence a striking rise of ornithine decarboxylase activity requires further study. In another experimental model in which enhanced crypt cell proliferation, associated with increased ornithine decarboxylase activity, was caused by intraluminal amine infusion, spermine and spermidine levels were not increased.

The current findings suggest also that an alternative pathway for intestine mucosal polyamine production, independent of ornithine decarboxylase activity, may have been activated after ischaemic injury. Polyamine interconversion pathways have recently been shown and in chicken duodenum putrescine is generated in the presence of DFMO through the combined activity of spermidine N-acetyltransferase and polyamine oxidase. Our observation of a failure of spermine and spermidine tissue levels to decline in DFMO-fed rabbits after ischaemic injury is consistent with the activation of this alternate pathway but it is clear that high levels of these polyamines in the DFMO group early after ischaemia, did not alter intestinal epithelial repair.

We thank Mr Mahmood Khan for his technical assistance. DL-difluoromethylornithine was kindly donated by Dr P. McCann, Merrell Dow Pharmaceuticals Inc, Cincinnati, OH. We are extremely grateful to Dr Margaret Eggo, Banting and Best Department of Medical Research, University of Toronto, for her assistance in pretreating radioactive ornithine facilitating its use in our ornithine decarboxylase assay, and to Dr Fred Keally, Department of Biochemistry, Hospital for Sick Children for his assistance with the spermine and spermidine assays.

This work was supported by a grant from the Medical Research Council of Canada. Dr Guzman received scholarship support from the Anna Bradley Springer fund, University of Toronto and from the Hospital for Sick Children Foundation during the course of these studies.
