Effect of insulin induced hypoglycaemia on in vitro uptake of 3-O-methylglucose by rat jejunum

A K BANERJEE, K RAJA, AND T J PETERS

SUMMARY Acute hypoglycaemia (<2.0 mmol/l) selectively increased in vitro 3-O-methylglucose uptake by rat jejunum. In contrast, uptake of 3H-phenylalanine or 59Fe (III) was unchanged in the hypoglycaemic animals. The hypoglycaemia was accompanied by decreased tissue adenosine nucleotide energy charge. The increased uptake was phlorrhizidin-inhibitable and therefore reflected increased Na+ dependent glucose carrier activity. Cycloheximide did not block the increased 3-O-methylglucose uptake, implying that the mechanism is not the result of increased de novo carrier protein synthesis.

Rats rendered chronically diabetic show various changes in small intestinal function and structure including enhanced sugar transport, increased activities of brush border hydrolases and of glycolytic enzymes, depressed calcium absorption and, in the longer term, morphological changes. Early studies in alloxan induced diabetes in rats indicated that glucose absorption was accelerated in diabetes and this effect was prevented by insulin. 3-O-methyl D-glucose absorption by isolated perfused jejunal segments was also increased in alloxan induced diabetes and in rats where diabetes was induced by anti-insulin serum. Another study confirmed increased intestinal glucose absorption in streptozotocin induced diabetes, but with a less marked rise in glucose absorption in anti-insulin serum induced diabetes. There was no change in glucose absorption when insulin was added to the media.

A study carried out in man also showed that intestinal glucose absorption was significantly greater in diabetic than in normal subjects. Insulin administration did not alter glucose absorption in either patient group, even though it always depressed the blood glucose. In contrast, starvation induced hypoglycaemia in the rat produced accelerated glucose absorption by everted sacs of rat upper ileum. Little is known, however, of the mechanism of the hypoglycaemic response. We have therefore characterised and used an in vitro technique for determining 3-O-methylglucose transport by isolated jejunal tissue slices and investigated the changes after insulin induced hypoglycaemia.

Methods
ANIMALS Five week old male Sprague-Dawley rats (140–160 g) were used throughout. They were fed a standard rodent diet (Labsure LAD 1 diet Lavender Hill, Manea, Cambridgeshire).
IN VITRO UPTAKE The technique used has been fully validated for use with a variety of nutrients. In particular, 52Cr EDTA has been shown in several studies to be an excellent choice for an extracellular marker when measuring 3-O-methylglucose uptake. In brief, a piece of intestinal tissue was removed 3 cm distal to the duodenojejunal junction, cut longitudinally and sectioned into fragments (5–15 mg wet weight). After a brief rinse in buffered HEPES (N-2-hydroxyethane piperazine N-2 ethane sulphonic acid)-oxygenated medium (16 mmol/l HEPES-KOH, 125 mmol/l NaCl, 3-5 mmol/l KCl, 1 mmol/l CaCl₂, 10 mmol/l MgSO₄, pH 7.4), the fragments were trans-

(r=0.83; p<0.01) and at varying medium concentrations showed Michaelis-Menten kinetics (Fig. 1b). Calculation of $K_m$ and $V_{max}$ was by direct linear plots (Fig. 2). After 20 minutes incubation in the buffer medium, the tissue slices undergo progressive deterioration and ultimately cellular death. Accordingly, the method is reliable for incubation periods of up to 20 minutes. Five minutes was chosen as the standard incubation time for the experiments reported here as (from Fig. 1a and b) it will be seen that, first, it is on the linear slope of the time course curves, and therefore is a more reliable measure of cellular kinetics and, second, there will be minimal risk of any cellular degeneration at this stage in the experiment.

EFFECT OF INSULIN INFUSION

The blood glucose in control and insulin treated rats are shown in Figure 3. Both the low and high doses of insulin produced a fall in the blood glucose over the first 10 to 15 min followed by recovery phase. In vitro jejunal glucose uptake was assayed at 15, 30, and 60 min after the insulin injections and showed Michaelis Menten kinetics (Fig. 4). Only the 30 minute values are shown as the effect is greatest at this time with 5 U/kg insulin injection. At 15 minutes and 60 minutes there was no significant difference in uptakes with insulin injection versus controls: however, ouabain and phlorrhizin inhibitor was seen at both these times. The apparent kinetic parameters were shown in Table 1. Addition of insulin to the incubation medium did not affect the in vitro 3 MG uptake. In separate experiments in vitro 3MG uptake was deter-

mined with 1 mmol/l ouabain in the incubation medium and the results are shown in Figure 4: in both control and insulin treated animals uptake was fully inhibited by ouabain. Intestinal 3 MG uptake in insulin treated animals in whom blood glucose levels were 'clamped' also showed saturation kinetics but the kinetic parameters did not differ from control animals (Table 1).

The specificity of the response to insulin infusion was investigated by estimating 3Fe (III) and [H]-phenylalanine uptake in vitro. As seen in Table 2 no significant differences were found between the control and the insulin treated groups. Intestinal 3 MG uptake in insulin treated and control animals treated with cycloheximide are shown in Table 1. The increased 3 MG uptake in the hypoglycaemic animals receiving cycloheximide were similar to that seen in animals receiving insulin alone. When cycloheximide was administered to control animals no blood glucose changes were seen within the first two hours. Insulin treated rats had reduced ATP levels and energy charge with increased ADP and AMP compared with controls. The total nucleotide level was unaffected (Table 3).

Discussion

This study shows that marked hypoglycaemia increases absorption of 3-0-methylglucose by the rat jejunum. The effect is maximal 30 minutes after the injection of the hormone and is not seen with lower doses of insulin and is prevented by maintenance of normal blood glucose. The kinetic studies show that the effect is the result of an increase in the apparent V max for 3 MG uptake - that is, increased carrier number or activity. The range of medium glucose concentrations used was from 5 to 250 mmol/l. The lower limit of the range was chosen to be well below Km to allow accurate determination of the Km. The upper limit did pose problems regarding the osmolality of the incubation medium: this was partly compensated by up to a 30% reduction in the NaCl content of the buffer at the higher concentrations of 3 MG. The spurious controversy between real and apparent Km does not apply, although Debnam and Levin claimed that the true Km for active absorption for a variety of sugars is about three times less than that of the apparent Km, the 3Cr permeability probe has been shown in many subsequent studies to correct for this.

The results in the insulin+glucose treated rats which show no change in the 3 MG uptake indicates that hypoglycaemia per se and not the increased plasma insulin level is the mediator of the enhanced 3 MG uptake. To confirm this it would be necessary to carry out further studies to exclude other factors - for example, hyperglucagonaemia, as concentrations of pancreatic glucagon would be expected to rise during acute hypoglycaemia. When glucagon (1 μg) was administered iv in control animals, however, no change in intestinal glucose uptake was observed.

No changes in 3 MG uptake were seen when jejunal slices were incubated with the medium containing 1000 U/l insulin. This also suggests that the

phenomena is not a direct insulin effect on the gut. An alternative explanation could be that in a preparation that has no vascular clearance, insulin failed to penetrate the muscle layer, and did not reach the enterocyte receptors.

The specificity of the response for glucose was confirmed by the absence of any effect of hypoglycaemia on intestinal "Fe (III) or phenylalanine uptake in the hypoglycaemic animals. The results of ouabain studies would indicate that the increased glucose uptake is mediated by the Na\(^+\) dependent carrier. Phlorrhizin, a specific competitive inhibitor of glucose uptake at the brush border, is a more useful reagent and the results provide strong evidence that a Na\(^+\) dependent carrier is indeed involved.

The results of the nucleotide analysis show that the mucosal energy charge of the hypoglycaemic animals is reduced compared with the controls and presumably is caused by the hypoglycaemia. It is worth noting that the excised intestinal tissue was freeze clamped so that nucleotide levels in the incubated tissue itself could be determined. This accounts for the lower energy change values compared with in situ freeze clamped tissue.\(^{17}\)

The failure of cycloheximide to prevent the increased glucose uptake in the hypoglycaemic animals suggest that de novo synthesis of glucose carrier was not responsible for the increased 3 MG uptake. Possible mechanisms therefore would include increased recruitment of glucose carriers to the brush border membrane or increased carrier activity (turnover number).

The acute regulation of glucose absorption, transport and metabolism in rat small intestine has been studied in vivo but these studies have mainly investigated the hyperglycaemic state.\(^{18-20}\) These changes appeared to correlate with the inhibition of two mucosal enzymes, pyruvate dehydrogenase (EC 1.2.2.2) and phosphofructokinase (EC 2.7.1.11). Esposito et al\(^{21}\) found that hyperglycaemia caused an increase in net transport of glucose, sodium and water in everted rat jejunum without modifying their intracellular concentrations. This observation was explained by an effect on the glucose carrier in the basolateral membrane of the enterocyte.\(^{22}\) Maenz and Cheeseman\(^{23}\) found that hyperglycaemia did not affect the rate of glucose uptake across ileal basolateral vesicles but did cause a 78% increase in the initial rate of carrier mediated D-glucose uptake across jejunal basolateral vesicles. They suggested that an increase in the number of functioning glucose transporters in the basolateral membrane may play a role in the acute increase in glucose absorption by the jejunum of the hyperglycaemic animal. Interestingly, the latter study also implied a rapid rate of carrier turnover in the basolateral membrane of the enterocyte. Thus induction of the glucose transporter in the basolateral membrane with enhanced active transport across the brush border would maximise net glucose absorption by the jejunum of the hyperglycaemic animal.\(^{24}\) It is possible that similar adaptive mechanisms may occur in acute hypoglycaemia.\(^{21-28}\)
