Pancreatitis after sphincter of Oddi manometry

P Rolny, B Anderberg, I Ihse, E Lindström, G Olaison, A Arvill

Abstract
The nature, frequency, severity, and possible causes of complications after 207 sphincter of Oddi manometry measurements were studied in 146 patients. Acute pancreatitis was diagnosed in 6% (12 of 207) of the investigations and in 8% (12 of 146) of the patients examined. The pancreatitis was mild in all patients. After cannulation of the pancreatic duct, acute pancreatitis occurred in 10 of 95 (11%) patients compared with one of 93 (1%) when the manometry catheter entered the bile duct only (p<0.02). Seven (58%) of the patients who developed acute pancreatitis, however, were found to be suffering from chronic pancreatitis. Some 26% of all sphincter of Oddi manometry measurements on patients with this diagnosis were complicated by an acute attack of pancreatitis compared with 3% (p<0.001) in patients without signs of chronic pancreatitis. In all patients the pancreatitis developed within three hours of manometry.

We conclude that pancreatitis may occasionally follow sphincter of Oddi manometry measurement, even in patients without pancreaticobiliary disease, and that underlying chronic pancreatitis constitutes a definite risk. Sphincter of Oddi manometry measurement in control subjects should therefore be performed only in centres where the safety of the procedure has been established, and the presence of chronic pancreatitis should be excluded beforehand. Cannulation of the pancreatic duct should be avoided. Manometry can be safely performed, however, as an outpatient procedure.

Although endoscopic manometry of the sphincter of Oddi has been increasingly used in clinical practice for more than a decade, very little is known about the nature, frequency, and severity of its complications. This is astonishing since experience from endoscopy with retrograde cholangiopancreatography (ERCP) shows that manipulation of the papilla as well as cannulation of the duct system, even without contrast injection, bears a small but definite risk of complications and in particular of acute pancreatitis.

We report on the complications we encountered in performing sphincter of Oddi manometry over a four year period.

Patients and methods

PATIENTS
This report is based on 207 consecutive manometric investigations of the sphincter of Oddi in 146 patients. The measurements were performed between 1984 and 1987. The patients had been referred because of postcholecystectomy right upper quadrant pain, suspected of being caused by biliary dyskinesia (n=133) or because of chronic pancreatitis with suspected outflow obstruction (n=13).

In addition to sphincter of Oddi manometry, the patients were also investigated by routine laboratory tests, liver tests, ultrasound, secretin test, upper gastrointestinal endoscopy, ERCP, and barium enema as indicated. The ERCP was always performed at least three weeks apart from manometry.

The patients were divided into the following groups based on results of these investigations as well as on a follow up period of at least one year.

Group 1 – patients with biliary dyskinesia (n=24). The clinical suspicion was supported by grossly abnormal manometry findings. One patient, in whom cannulation of the papilla by the manometry catheter failed, was also included as surgical sphincteroplasty resulted in pain relief during the year of follow up.

Group 2 – patients with pain unrelated to the pancreaticobiliary region (n=98). This group consisted of 88 patients with normal manometry measurements as well as eight patients in whom pull-through manometry failed. In our experience differentiation between normal and abnormal manometry results is clinically relevant as most patients with abnormal sphincter of Oddi pressure, if untreated, continued to experience pain, whereas those with normal results either improve over time or are diagnosed as having other diseases unrelated to the pancreaticobiliary region.

Group 3 – chronic pancreatitis (n=24). In 13 of these patients the diagnosis had been established before manometry. These 13 suffered from episodes of upper abdominal pain lasting from some hours to several days and an outflow obstruction was suspected. The remaining 11 patients initially showed a clinical picture of biliary dyskinesia characterised by episodes of biliary-like pain. In these the diagnosis of chronic pancreatitis was, in accordance with internationally accepted criteria, supported by at least two abnormal results from the following investigations: serum pancreatic-isoamylase, secretin test, ERCP, glucose tolerance test, and faecal fat excretion (when coeliac disease was excluded). In all of the patients manometry was performed during a quiet phase in the disease, at least four weeks after an exacerbation.

ENDOSCOPIC MANOMETRY
Because our method has already been described

in detail, only some points of major interest will be discussed here.

Before investigation the patients were sedated with intravenous diazepam (2.5–15 mg). As shown previously this drug does not exert any appreciable effect on the sphincter. No other drugs were used. For duodenoscopy a standard fibre endoscope (Olympus JF1T) was used. Between 1984 and 1985 the triple lumen manometry catheter was perfused with bubble-free water at a rate of 0.25 ml/minute and between 1985 and 1987 with isotonic saline at the same rate. A minimally compliant hydraulic capillary infusion system was used. The cannulation procedure was regarded as easy if less than four attempts were needed to insert the cannula into the selected duct. Identification of the duct that had been cannulated was based on the appearance of colourless pancreatic juice or bile in the catheter upon gentle aspiration. The reliability of this method has been documented previously.

The pancreatic duct alone was cannulated on 56 occasions and both pancreatic and bile ducts on 39 occasions. Thus, the manometry catheter entered the pancreatic duct on a total of 95 occasions, and on 93 occasions the bile duct only was cannulated. Only one registration was performed from either duct at any manometry session. Two of the patients had three and 57 had two manometry investigations at least two weeks apart, whereas the remaining 87 were investigated once only.

On most occasions the perfusion time of any duct did not exceed 20 minutes. It was longer (25–40 minutes) on only nine occasions in six patients.

The manometry was performed as an outpatient procedure with the patients remaining at the hospital for four to five hours for observation. Those who were not completely free of symptoms by that time were admitted to hospital until all their symptoms resolved. No food was allowed for the first three hours of observation but thereafter a cup of tea and a sandwich were offered.

DEFINITION OF POSTMANOMETRY PANCREATITIS

Patients who developed upper abdominal pain accompanied by raised serum amylase or pancreatic isomylase activities after the manometry procedure were classified as having acute pancreatitis. A fifth of serum amylase or pancreatic isomylase were determined in asymptomatic patients our definition comprises only clinically evident pancreatitis.

For statistical analysis a χ² test was used, using Yates’s correction.

Results

The only type of complication found was acute pancreatitis. Other complications such as sepsis, pseudocyst formation, cholangitis, or adult respiratory distress syndrome were not encountered.

Altogether 12 episodes of pancreatitis were recorded after 207 manometry procedures (6%) in 146 patients (8%). Pancreatitis developed in 11 of 188 (5.3%) investigations when the pancreatic duct or bile duct, or both, were cannulated and in one of 19 (5.2%) when the cannulation of the papilla failed.

According to accepted criteria the attacks of pancreatitis were clinically mild in all patients (Table I). The hospital stay ranged from four to 12 (mean eight) days. In none of the patients were any long-term complications detected clinically or by ultrasound or computed tomography.

As shown in Table I the intraductal pressures were normal or only slightly raised in the subjects who subsequently developed pancreatitis and remained unchanged during the manometry procedure. In four of the patients who developed pancreatitis the manometry catheter was perfused with bubble-free water and in nine the isotonic saline was used. The perfusion times in each of the patients are also shown in Table I.

In 10 of the 12 manometry investigations that were followed by pancreatitis, the pancreatic duct was cannulated with or without concomitant cannulation of the bile duct (Table I). When the pull-through manometry investigations are considered, pancreatitis developed on 10 of 95 (11%) occasions when the pancreatic duct was cannulated and on one of 93 (1%) occasions when the bile duct only was cannulated (p<0.02) (Table II). Pancreatitis was not more frequent when both the pancreatic and bile ducts

were cannulated (5-1%) than when the pancreatic duct alone was cannulated (16%). As shown in Table I, seven of 12 (58%) patients with postmanometry pancreatitis had chronic pancreatitis. In patients with this diagnosis pancreatitis followed in 26% of all manometry investigations and in 32% when the catheter was inserted into the pancreatic duct (Table II). By comparison, in patients without pancreatic disease, pancreatitis occurred in four of 161 (2.5%) manometric studies (p<0.001) and in 4% of those in whom the pancreatic duct was cannulated (p<0.001). Even in these patients pancreatitis occurred somewhat more frequently after pancreatic duct cannulation (4%) than after bile duct cannulation (1%) but the difference was not statistically significant. There was no difference in frequency of pancreatitis between the groups of patients with and without biliary dyskinesia as pancreatitis occurred after one of 39 (2.5%) investigations in patients with biliary dyskinesia and after three of 122 (2-3%) investigations in patients with unrelated pain.

Difficulty in performing cannulation did not, per se, seem to represent an obvious risk factor since, as mentioned above, pancreatitis followed only one of the 19 (5-2%) cannulations which ultimately failed. For most pull-through manometry investigations the cannulation was easy. In the patients in cases 6 and 7, however, the pancreatic duct was cannulated three and four times respectively and in the patient in case 11 prolonged pancreatic duct manometry – that is, 30 minutes – was followed by repeated cannulations of the same duct in an endeavour to enter the bile duct. It is of interest to note that two investigations were performed on both this patient and the patient in whom cannulation failed. Although similar conditions prevailed on both occasions, pancreatitis followed only one of these. Patient 12 was the only one who developed pancreatitis after bile duct manometry alone. No contributing factors could be identified.

In all 12 patients pancreatitis developed within three hours of the procedure.

**Discussion**

Until recently endoscopic manometry of the sphincter of Oddi has been regarded as a procedure that is virtually free from complications. Then it was stated at the international workshop on sphincter of Oddi in Rome in 1985 that pancreatitis could occasionally occur in patients with pancreatic or biliary abnormalities or when manometry was performed in conjunction with ERCP. In two recent studies, so far published in abstract form only, postmanometry pancreatitis occurred in 6-5% and 19% of subjects respectively. In addition, sepsis, pseudoocysts, and adult respiratory distress syndrome were occasionally observed. Most of the authors, however, performed ERCP and manometry at the same session. Although no correlation was found between performing the procedures at different times or the order in which they were performed, the relative contribution of ERCP can not be disregarded. This report is the first comprehensive study of complications associated with sphincter of Oddi manometry. It is based on a comparatively large number of manometric investigations performed at least three weeks apart from ERCP. Thus, the findings are solely related to the manometry procedure.

In contrast to a previous report pancreatitis was the only complication occurring in the 6% of our manometric studies that were followed by complications. Although none of our patients experienced severe pancreatitis or any longterm sequelae, it caused a prolonged stay in hospital in four patients. Moreover, since pancreatitis can, irrespective of aetiology, worsen and become severe it is most important to look for possible causes.

An increase in intraductal pressure during the procedure was not found to be a causative factor in this study. Likewise, intraductal hypomosmality has to be discarded as a factor since the frequency of pancreatitis was not affected by replacing water with isotonic saline for perfusion of the manometry catheter. On the other hand, cannulation of the pancreatic duct seems to constitute a risk as this duct was cannulated on all but manometry procedures that were followed by pancreatitis. More than half the number of attacks, however, occurred in patients with chronic pancreatitis and this seems to be a major risk factor. This is important since in almost half of our patients the diagnosis of chronic pancreatitis was unknown at the time of manometry. Thus, chronic pancreatitis should be excluded before referring a patient for sphincter of Oddi manometry. On the other hand it is difficult to explain the high frequency of acute postmanometry pancreatitis in our patients with chronic pancreatitis, as ERCP in these subjects was followed by only one case (4-6%) of mild pancreatitis. Also, in our experience, which comprises nearly 7000 ERCP investigations, pancreatitis after ERCP is only slightly more frequent in patients with chronic pancreatitis than in those without that diagnosis.

Whether patients with biliary dyskinesia are at increased risk for postmanometry pancreatitis as suggested by King et al cannot be judged from our study as pancreatitis followed only one of the pull-through manometry investigations in this patient group. In King’s study, however, an unspecified number of patients with hyperamylasaemia were included and their findings may reflect a relatively high proportion of patients with pancreatitis rather than biliary dyskinesia.

Contrary to previous opinion, our results show that postmanometry pancreatitis may occasionally develop even in subjects without any underlying disease. A recent report of severe postmanometry pancreatitis in a healthy volun-

teer supports our findings. Although this report does not mention which duct was cannulated, what is remarkable is that the total cannulation time was only seven minutes. This is consistent with our observation that short manometry by no means prevents postmanometry pancreatitis. On the other hand, our results suggest that the risk is negligible, irrespective of underlying disease, if only the bile duct is cannulated. Although our study does not suggest that the mechanical trauma, due to repeated attempts at cannulation or repeated cannulation, increases the risk, this cannot be definitely excluded. Furthermore, such a technique carries a risk of manometric artefacts and should also, for this reason, be avoided.

Our observation that postmanometry pancreatitis developed invariably within three hours of manometry is also clinically important as it suggests that the procedure may safely be done on an outpatient basis. Finally, our results suggest that sphincter of Oddi manometry in healthy volunteers should only be undertaken in centres where the safety of the procedure has been established.

We thank Mrs. Ann-Charlott Sundh-Persson for excellent secretarial work, Derek Filbey for correcting the English, and Anders Arleback for skilful technical assistance.
