Acute *Helicobacter pylori* infection: clinical features, local and systemic immune response, gastric mucosal histology, and gastric juice ascorbic acid concentrations

Abstract

The symptomatology of a case of acute infection with *Helicobacter pylori* is described, together with the accompanying changes in gastric mucosal histology, local and systemic humoral immune response, and gastric ascorbic acid concentration. The patient was an endoscopist, previously negative for the carbon-14 urea breath test, who had a week of epigastric pain and then became asymptomatic. *H pylori* was detected by culture of antral biopsy specimens and was still present after 74 days. Five days after infection the histological findings showed acute neutrophilic gastritis; by day 74 changes of chronic gastritis were evident. The patient seroconverted by IgG enzyme linked immunosorbent assay by day 74, but a mucosal IgM and IgA response was evident as early as day 14. Infection was accompanied by a transient hypochlorhydria but a sustained fall in gastric juice ascorbic acid concentration.

It is now widely accepted that *Helicobacter pylori* is the cause of chronic gastritis, and a large proportion of the world population is chronically infected with this organism. The only descriptions of the illness accompanying the onset of infection come from two experimental ingestion studies, retrospectively from gastric intubation studies in which iatrogenic infection occurred, and from a single case report of spontaneous infection. These may not be representative. We have had the serendipitous opportunity to examine in detail the symptoms, changes in local and systemic immune response, and gastric histology accompanying a further case of spontaneous infection with this organism. We have also been able to determine gastric juice ascorbic acid concentrations before and after infection. Ascorbic acid is thought to be protective against gastric cancer and is secreted by the normal stomach. This secretion is impaired in the presence of *H pylori* associated chronic gastritis.

Case report

CLINICAL FEATURES

A 30 year old gastroenterology research fellow (GMS) was engaged in research which involved aspirating and handling gastric juice. A 14C-urea breath test had been negative 2.5 years previously. Over the course of an evening he developed severe epigastric pain which occurred in cramping waves lasting 15 to 30 seconds at intervals of a couple of minutes. On the first day he had mild headache and malaise but remained afebrile. He had occasional mild nausea but did not vomit. The pains woke him every night between 3.00 am and 5.00 am. They were transiently exacerbated but then relieved by eating. The symptoms began to ease on day 5 and had completely resolved by day 7.

ENDOSCOPIC FINDINGS

Upper gastrointestinal endoscopy on day 5 showed only gastritis with a gaping pylorus. Aspirated gastric juice was neutral with a pH of 7.0. On day 14 gastric erythema was still present but less pronounced, and gastric juice had a pH of 7.5. At day 74 endoscopic appearances were within normal limits, and aspirated gastric juice was acid with pH 2.

MICROBIOLOGICAL FINDINGS

Two and a half years before the illness a 14C-urea breath test had been completely negative. On day 5 a biopsy urease test (CLOtest, Delta West, Australia) was negative after one hour but positive after 24 hours’ incubation, and *H pylori* was successfully cultured although growth was scanty. On day 14 both biopsy urease test and culture were negative. At day 74 a biopsy urease test was negative but *H pylori* was again successfully cultured. A 14C-urea breath test (Europa Scientific, Crewe, England) was positive at day 91 and day 342.

These infiltrate the surface epithelium, which is appreciably degenerate and shows cellular exfoliation. Haematoxylin and eosin. Original magnification ×64.
HISTOLOGICAL FINDINGS

Gastric biopsy specimens taken on day 5 showed appreciable surface epithelial degeneration with increased cell exfoliation. The superficial lamina propria contained many neutrophil polymorphonuclear leucocytes which infiltrated the surface and pit-lining epithelium and were present as a surface exudate (Fig 1). The appearances were those of an acute neutrophilic gastritis and were equally prominent in antral and body mucosa. Although a few micro-organisms including diplococci were seen in the surface exudate, no convincing helicobacters were identified with the modified Giemsa stain. Biopsy specimens from day 14 were essentially similar in showing an acute neutrophilic gastritis in antrum and body, although a minor increase in chronic inflammatory cells could be discerned (Fig 2). Again, *H pylori* were not positively identified. Duodenal biopsy specimens were normal.

At day 74 biopsy specimens from both antrum and body showed a moderate increase in lymphocytes and plasma cells in the superficial lamina propria. There was foveolar hyperplasia and neutrophil polymorphonuclear leucocyte infiltration around the pit-isthmus region. The appearances were those of a diffuse chronic gastritis with mild activity (Fig 3). On this occasion scanty helicobacters were seen.

IMMUNOLOGICAL FINDINGS

Methods

Systemic and mucosal humoral responses to *H pylori* were investigated by enzyme linked immunosorbent assay (ELISA) and immunoblotting. Sera were assayed for *H pylori* IgG antibodies by ELISA using an ultracentrifuged sonicated antigen preparation from one strain of *H pylori*. Positivity was determined by reference to *H pylori* positive and negative control sera (ELISA sensitivity 97%, specificity 95%). GASTRIC JUICE ASCORBIC ACID

Method

Ascorbic acid and its oxidation product dehydroascorbic acid together comprise total vitamin C. Only ascorbic acid is an antioxidant, although both compounds are antiscorbutic. The concentrations of ascorbic acid and total vitamin C in gastric juice were determined at each endoscopy and also three times by nasogastric intubation, 170 days before and 37 and 161 days after the start of the clinical illness. On these occasions a nasogastric tube was passed in the morning after an overnight fast and was placed on continuous suction. The volume of gastric juice aspirated every 15 minutes for at least 90 minutes was measured, the gastric juice pH was determined, and a 1 ml aliquot of juice was put straight into 1 ml of a 2% solution of metaphosphoric acid and frozen at −70°C. An intravenous injection of 500 mg of ascorbic acid was given at 45 minutes. On the first occasion blood was drawn into a heparinised container before and 90 minutes after the injection, while...
on the last two occasions it was drawn at 15 minute intervals throughout the procedure and also three minutes after injection. After centrifugation, 1 ml of plasma was added to 2 ml of 2% metaphosphoric acid and frozen at −70°C. Gastric juice and plasma samples were then analysed within two weeks for ascorbic acid and total vitamin C concentrations using a previously developed high performance liquid chromatography method.  

Results

Before the illness fasting gastric juice ascorbic acid and total vitamin C concentrations were approximately equal to plasma, and rose rapidly after intravenous ascorbic acid (Table, Fig 4). At 37 days ascorbic acid was scarcely detectable in gastric juice either fasting or after injection, although a small amount of total vitamin C was recovered from gastric juice after injection (Table). Gastric juice pH remained neutral throughout. At 161 days gastric juice was once more of acid pH but both ascorbic acid and total vitamin C concentrations remained low and rose only slightly after intravenous ascorbic acid (Table, Fig 4).

Discussion

Even in the absence of gastric histology before the clinical illness the initial negative 'C urea breath test, serology, and subsequent seroconversion indicate that the symptoms corresponded to acute infection with H pylori. There is no doubt that the patient was ultimately positive for H pylori, as it was detected by several techniques. It could be argued that the symptomatic illness and hypochlorhydria were due to another unidentified aetiological factor, which allowed colonisation by H pylori. This suggestion is impossible to refute but on the basis of Occam’s razor it is unnecessary. Firstly, the association between H pylori and chronic gastritis cannot be doubted and elimination of the organism results in healing of gastritis. Secondly, the symptoms closely resembled those described by Arthur Morris after voluntary ingestion of H pylori, and were broadly similar to those of Barry Marshall. Arthur Morris also experienced hypochlorhydria and developed chronic gastritis. Thus we have described no phenomena that require additional hypothetical causes.

We propose that at least some people who are acutely infected with H pylori experience a brief self limiting episode of dyspepsia: certainly about 60% of patients infected iatrogenically became symptomatic. It is not surprising, however, that this syndrome has not been clinically recognised before, as by the time such patients are referred their symptoms will have settled, and the endoscopic appearances would not be especially remarkable in those who are investigated. If looked for hard enough further cases may come to light. For example, we have recently seen a 20 year old woman who required admission to hospital because of severe cramping epigastric pains lasting one week. Although endoscopy on day 7 was unremarkable, the fasting gastric juice was of neutral pH, and gastric biopsy specimens showed histological appearances of H pylori positive acute neutrophilic gastritis identical to that described above. Thus we believe that acute H pylori infection should now be considered in the differential diagnosis of acute epigastric pain.

A recent study has shown a high incidence of H pylori positive serology in endoscopy staff, and it is likely that our patient became infected either by inhalation of spray from the biopsy channel of a fibre endoscope or while handling gastric juice samples for research. His wife was seronegative by ELISA for H pylori.

The histological features early in the illness were unusual and distinctive. Acute gastritis is usually seen in the context of non-steroidal anti-inflammatory drug use or excessive alcohol ingestion and presents histologically as an erosive or haemorrhagic gastritis with epithelial degeneration, foveolar hyperplasia, oedema and congestion of the lamina propria, and interstitial haemorrhage. Neutrophil polymorphonuclear leucocytes (and other inflammatory cells) are scanty or absent. The finding of conspicuous infiltration in acute H pylori infection distinguishes the mucosal response from that seen in drug or alcohol related injury. Acute neutrophilic gastritis is rarely found in endoscopic biopsies. In the pre-H pylori era it was a recognised response to other bacterial infections of the stomach, but these were largely confined to severely debilitated patients and at necropsy as a supportive or 'phlegmonous' gastritis principally of the submucosal layer of...
the stomach wall.\textsuperscript{11} \textit{H pylori} has been incriminated in an acute 'purulent' gastritis,\textsuperscript{11} but up to now the only histological description of the early response to proven infection is contained in the reports of Marshall \textit{et al}\textsuperscript{12} and Morris and Nicholson.\textsuperscript{13} This is the first detailed account of the appearances after a 'naturally' acquired infection with \textit{H pylori}.

It is notable that early in the illness it was not easy to positively identify \textit{H pylori} by several different techniques, and this difficulty may be related to the transient hypochlorhydria. It seems that \textit{H pylori} survives but does not flourish in the stomach when gastric juice is of neutral pH: this is evident in patients treated with omeprazole, which suppresses but does not eradicate the organism.\textsuperscript{14,15}

Immunoblotting showed that a local immune response to \textit{H pylori} was evident in this subject soon after the onset of symptoms, at which time there was no evidence of a systemic IgG response to \textit{H pylori} by either immunoblotting or ELISA. This is compatible with an acute infection. The persistence of the mucosal IgM response at 74 days is of interest as there is little evidence of a specific antral IgM response by immunoblotting in patients with chronic gastritis (J Crabtree, unpublished observations), such patients having a strong local IgA response to \textit{H pylori}.\textsuperscript{16} The occurrence of a rapid local immune response after the onset of symptoms reinforces a pathogenic role for \textit{H pylori}.

The first major \textit{H pylori} antigen recognised systemically by IgG was the 12 kDa protein. This protein is thought to be a surface protein and is not present in all \textit{H pylori} strains.\textsuperscript{17} The increased systemic IgG recognition of \textit{H pylori} proteins between days 138 and 198 in this subject shows that serological responses to \textit{H pylori} take time to develop fully.

We have previously shown that many people with normal gastric histology have high concentrations of ascorbic acid in gastric juice, but that intragastric concentrations are much lower in patients with \textit{H pylori} associated chronic gastritis.\textsuperscript{18} Preinfection fasting intragastric concentrations in this patient were only approximately equal to and not greater than plasma concentrations, but we have observed this in other normal subjects.\textsuperscript{19} Intragastric concentration rose rapidly after intravenous injection. However, 37 days after infection during the hypochlorhydric phase there was virtually no ascorbic acid or total vitamin C in the stomach either in the fasting state or after the intravenous supplementation. Although ascorbic acid is relatively unstable in neutral gastric juice this is only because of its rapid oxidation to dehydroascorbic acid, and we have shown that in vitro virtually 100% of ascorbic acid added to neutral gastric juice can be recovered as total vitamin C after an incubation period of one hour, most of it by then in the form of dehydroascorbic acid.\textsuperscript{20} That \textit{H pylori} associated gastritis represents a failure of secretion and not merely pH dependent destruction of ascorbic acid is confirmed by the fact that gastric juice ascorbic acid concentration remained low and incremented poorly even when recovery from hypochlorhydria had occurred at 161 days. Initially the poor ascorbic acid secretion was paralleled by a failure of hydrogen ion secretion, but there is evidence that the two secretory mechanisms are independent\textsuperscript{21} and this is supported by the findings here at 161 days.

There is some evidence that \textit{H pylori} does not tolerate high ascorbic acid concentrations well,\textsuperscript{22} and thus a reduction of ascorbic acid concentration in the stomach may favour \textit{H pylori}. The effect on the host is to decrease antioxidant potential in gastric juice and remove a putative protective factor against gastric cancer. This may be an important factor in the association between chronic gastritis and gastric cancer.

We conclude that infection with \textit{H pylori} gives rise to a distinctive syndrome of cramping epigastric hunger pains which are accompanied by a transient fasting achlorhydria and a characteristic histological picture of acute neutrophilic gastritis. The organism may be difficult to find during the period of hypochlorhydria. The symptoms are self limiting, but infection may become chronic and is accompanied by a local and then a systemic immune response. Gastric antioxidant defences in the form of gastric juice ascorbic acid are impaired.
