Risk factors for extensive ulcerative colitis and ulcerative proctitis: a population based case-control study

S-M Samuelsson, A Ekbom, M Zack, C G Helmick, H-O Adami

Abstract
To examine socioeconomic factors, dietary and other personal habits, and medical history as risk factors for ulcerative colitis, we studied 167 (98%) of all prevalent cases of ulcerative colitis diagnosed in Uppsala county from 1945 to 1964 and 167 age and sex matched population controls. Ulcerative colitis patients were less likely than controls to be current cigarette, pipe, or cigar smokers (odds ratio (OR)=0.44; 95% confidence limits (CL)=0.25-0.78), but more likely to have symptoms induced by drinking milk (OR=4.63; 95% CL=2.15-9.93). Patients with ulcerative colitis do not differ in most of the socioeconomic, dietary and personal habits compared with the background population.

The aetiology of ulcerative colitis is unknown, but previous case-control studies have suggested as determinants changes in diet,1 smoking,2,3 socioeconomic status,4,5 and childhood events such as infections and early weaning.6,7 The results in the different studies have been contradictory, and none was population based.

In an epidemiological investigation carried out in central Sweden about 20 years ago, all 220 patients diagnosed with ulcerative colitis in one county from 1945 to 1964 were identified. A total of 170 patients were alive on 1 January 1967, and 167 (98%) volunteered to take part in a case-control study. This study investigated socioeconomic background, dietary, personal habits, and medical history. Information was also gathered on the progress and activity of the disease. The results were based on univariate summary statistics and were published as a thesis monograph.8,9 We have reanalysed these data using modern univariate and multivariate statistical methods for case-control studies. We also examined the presence of any differences between non-progressive ulcerative proctitis and more extensive ulcerative colitis.

Methods
PATIENTS
Uppsala County had a population of 146 000 in 1945 and 180 000 in 1964. Four hospitals within the County provided inpatient care during this period.

For the period 1945–1964 one of us (S-M S) retrieved and examined patient charts in all four hospitals with the following discharge diagnoses: chronic ulcerative colitis, ulcerative enterocolitis, ulcerative proctitis, non-ulcerative gastroenteritis and colitis, terminal ileitis, regional enteritis, diverticulitis of the colon, diverticulosis of the colon, unspecified diverticulitis, other colitis, severe colitis, chronic colitis, and chronic enterocolitis. At the major medical centre, the University Hospital in Uppsala, S-M S also examined an outpatient register for possible cases during this period. Finally, reports of all barium enemas carried out during the period in the three different radiography departments within the County were examined.

The medical history was reviewed in all cases meeting the diagnostic criteria for ulcerative colitis described by Evans and Acheson.10 Initially, 227 patients were identified with ulcerative colitis. A reevaluation of the diagnoses was done in 1970 because of a study of Crohn's disease in the same county11; in seven patients diagnoses of ulcerative colitis were changed to Crohn's disease leaving 220 patients. Almost every patient alive in 1967 underwent a medical examination, a sigmoidoscopy, and a barium enema, and 167 of the 170 (98%) eligible cases volunteered to take part in the case-control study.

DATA ELEMENTS
Through the patient charts and registers within the County, information was gathered for each case on gender, year of onset of symptoms, year of diagnosis, place of residence at time of onset of symptoms and in 1967, extent of disease at time of diagnosis, maximum extent of disease until 1967, extent of disease in 1967, and number of days hospitalised because of ulcerative colitis and other illnesses after diagnosis.

Through face to face interviews with patients and controls, information was gathered about socioeconomic status of the father at time of
birth, marital status of parents, birth order, number of siblings, weaning, educational level, grade in mathematics during the last year in school, age at menarche, fitness for military duty, marital status, age at marriage, number of children before and after onset of symptoms, socioeconomic status and living conditions one year before onset of symptoms (the reference year for the matched control) and in 1967, diseases other than ulcerative colitis, number of days hospitalised and number of days of sick leave for ulcerative colitis and other diseases, smoking habits in 1967, age when starting smoking, drinking habits in 1967, and information about milk consumption in 1967. Socioeconomic status was classified as upper, middle, and lower and analysed for linear trend. To get an equivalent measurement in grams of total alcohol consumption per month, the number of bottles of beer, the number of glasses of wine, and the number of centilitres of hard liquor divided by 443595 were added.

To test the hypothesis that ulcerative proctitis and extensive ulcerative colitis have different aetiologies, we distinguished those designated as non-progressive proctitis among the cases where the colitis never had extended beyond the rectosigmoid junction from all other ulcerative colitis cases.

STATISTICAL ANALYSIS
The main measure of effect for a specific exposure in this study is the odds ratio (OR), an approximation to the relative risk that compares the odds of being exposed among cases to that among controls. For the matched case-control comparisons we used conditional logistic regression to estimate the odds ratio and its asymptotic 95% confidence limits (95% CL). We have expressed for some continuous variables the limits that include 95% of a population as 95% tolerance limits (95% TL). In these matched comparisons, we also used a randomised block design to analyse the effects of some continuous exposure variables without splitting them into arbitrary categories. In our multivariate analysis, we initially included all variables with p<0.25 in order not to miss possible confounding effects.

An association between case-control status and an exposure variable whose 95% CL of the OR exclude 1.00 or whose significance probability is less than or equal to 0.05 is considered statistically significant.

Results
FEATURES OF PATIENTS
Of the 220 patients, 50 died; this should be compared with an expected mortality of 29 patients using mortality data for the equivalent age groups during the time period studied in Sweden. Eleven patients died within two months of diagnosis; four of these died after surgical intervention. On death certificates for 30 cases, ulcerative colitis is not mentioned. In five patients, the diagnosis of ulcerative colitis occurs with a diagnosis of colorectal cancer. In two patients the diagnosis of ulcerative colitis occurs with liver disease, and in another, ulcerative colitis occurs with amyloidosis. In one 86 year old patient the cause of death was ulcerative proctitis. Finally, three patients, where the cause of death was ulcerative colitis, died at home without medical supervision.

Of the 167 patients 87 (52%) were male. At time of interview, on average 13 years (95% TL=4 to 35) had elapsed since the first attack of either diarrhoea or bloody stools indicating in some instances a substantial lag between the first attack and a subsequent diagnosis of ulcerative colitis. The median age at which patients started diarrhoea was 27 years (96% TL=4 to 61), the same median age as those started having bloody stools (95% TL=4 to 61). The age at which the patients started having diarrhoea was usually the same as when they started having bloody stools, but in 7% the diarrhoea preceded the onset of bloody stools by at least one year, and in 5% the reverse occurred.

The first hospital admission for ulcerative colitis occurred on average four years after onset (the median age at first hospital admission=31 with 95% TL=4 to 69). At first admission, 79% were considered only mildly affected, and only one patient required an operation. More than half of the 161 patients who underwent radiological examination without an operation had disease confined to the rectum at diagnosis. For those with limited disease at diagnosis, however, the extent of disease did increase after onset because only 38% had their disease confined to the rectum at its maximal extent. Almost 90% of the cases achieved complete remission or improved before discharge.

CASE-CONTROL ANALYSIS
Characteristics of the individual and of the family background did not generally distinguish the ulcerative colitis cases from their unaffected controls (Table I). Patients did not differ from controls with respect to birth order, how soon they were weaned, the number of siblings, their being or not being raised by both parents, or paternal (childhood) socioeconomic status. Patients had completed high school slightly but not statistically significantly more often than controls but still considered themselves more in need of further schooling (OR=3.67, 95% CL=1.02–13.14). Patients did not have higher math grades at school than controls, nor did male patients have lower military fitness rankings than their controls. Female patients (mean age 13.8 years) did not differ from their controls (mean age 13.7 years p=0.62) with respect to age at menarche.

The socioeconomic status, marital status, number of children, and degree of crowding within their homes (the number of persons per room) was not significantly associated with the occurrence of ulcerative colitis. Age at marriage was not delayed in cases (mean age=25.1 years) relative to that in controls (mean age=25.8 years; p=0.75). Patients were, however, more likely to have a rural residence compared with controls one year before onset of disease (OR=0.50; 95% CL=0.28–0.90) (Table II).
Patients were less likely than controls to be current cigarette smokers in 1967 (OR = 0.51; 95% CL = 0.29–0.87) but were as likely as controls to have been a former cigarette smoker (OR = 1.12, 95% CL = 0.55–2.29). Among ever smokers of cigarettes, patients began smoking at about the same age as controls, but current smokers smoked slightly fewer cigarettes per day than controls (OR = 0.95, 95% CL = 0.90–0.99). Patients were less likely than controls to be current smokers of either cigarettes, pipe or cigars (OR = 0.44, 95% CL = 0.25–0.78); patients resembled controls with respect to being a former smoker of cigarettes, pipe, or cigars (OR = 0.96, 95% CL = 0.46–1.99). At the time of interview (1967), patients complained more often than controls of having symptoms after drinking milk (OR = 4.63; 95% CL = 2.15–9.39) and reported drinking fewer glasses of milk per week (median 7) than controls (median 14). Patients drank about the same amount of alcohol (beer, wine, or hard liquor) as controls (Table III).

In a multivariate analysis, urban/rural status one year before onset of disease, smoking status, and whether there were symptoms after drinking milk at the time of interview remained statistically significant (Table IV). Their adjusted odds ratios did not differ from those in the univariate analysis; urban residence status a year before onset (OR = 0.53, 95% CL = 0.27–1.00), current smokers (OR = 0.53, 95% CL = 0.29–0.94), and symptoms after drinking milk (OR = 4.31, 95% CL = 1.94–9.57).

Risk factors for extensive ulcerative colitis and ulcerative proctitis: a population based case-control study

patients compared with those with ulcerative proctitis when treated as a linear variable.

Extensive ulcerative colitis patients were less likely than those with ulcerative proctitis to be current smokers of cigarettes, pipe, or cigars; among ever smokers, age at onset of smoking did not differ between the groups. Extensive ulcerative colitis patients were less likely to be former smokers than were ulcerative proctitis patients.

At the time of interview, extensive ulcerative colitis patients reported having symptoms after drinking milk more often than ulcerative proctitis patients, though the number of glasses of milk drunk per week did not differ between the groups.

Extensive ulcerative colitis patients did not drink more beer, hard liquor, or total alcohol than ulcerative proctitis patients. Extensive ulcerative colitis patients were, however, more likely to be wine drinkers than those with ulcerative proctitis.

Discussion

Our main finding was the absence of differences between patients with ulcerative colitis and population controls regarding most socioeconomic factors, and personal habits before and after diagnosis. Patients were more likely, however, to have a rural residence before diagnosis. After diagnosis, patients were less likely to be current smokers and more likely to have symptoms after drinking milk. Patients with non-progressive ulcerative proctitis did not differ from those with extensive ulcerative colitis with respect to most variables.

This study, to the best of our knowledge, the only population based case-control study of ulcerative colitis published so far. Almost all eligible patients and controls in the defined population were included, making selection bias unlikely. The retrospective methodology used to ascertain exposure may have introduced biases. The disease itself may have changed personal habits. Information regarding smoking and other personal habits was gathered in 1967 and habits at time of interview were analysed most often. In the few instances where information was gathered about habits before disease onset two to 22 years earlier, recall bias could be a problem. Incident cases who died before 1967, 50 of 220 (23%), were not included in this study. This fact could bias our results for risk factors such as smoking, which entails an excess mortality rate leading to an underestimation of the relative risk. The impact of this is, however, less than the number of 50 would lead us to believe. There was an expected number of 29 deaths among our patients which is close to that given in the death certificates. This means that the differential misclassification is likely to affect about 20 of the 220 patients being incident cases. Interview bias is unlikely because the interviewer (S-M S) did not have any previous hypotheses.

Three previous case-control studies have addressed the relationship of childhood events and ulcerative colitis. In most respects these results agree with ours. In the case of weaning, however, our study showed no difference between cases and controls, but two of the other studies showed a decreased proportion of breast feeding among future ulcerative colitis patients. The 'sheltered child' hypothesis has been proposed for ulcerative colitis, but has never been proved; and as in two previous studies, our patients did not differ from their controls in the number of siblings, birth order, or number of persons per room.

Two previous studies analysed urban/rural status at the time of diagnosis. One found a higher risk of ulcerative colitis among urban residents, but the other failed to detect any difference. Because our patients and controls were matched on urban/rural status, our results seem to indicate that patients with ulcerative colitis more often emigrate to urban areas after diagnosis compared with the general population. This finding casts some doubt on the hypothesis that urban residence is a risk factor for ulcerative colitis.

The absence of differences between patients and controls in alcohol consumption and marital status concurs with the results from another case-control study. In that study, patients had a higher educational level than controls, which agrees with our results for extensive ulcerative colitis but not for non-progressive ulcerative proctitis. The proportion of cases with more extensive disease, however, seems to be higher in this study than in ours, which could explain the differences.

Our study is to our knowledge the earliest that addressed the association between non-smoking and ulcerative colitis. After the first published study in 1982, many reports confirmed non-smoking as a feature of patients with ulcerative colitis. If the interviewer knows the study hypothesis and the case-control status of the person being interviewed, then this might bias a currently performed study. In our study, however, information was gathered in 1967, before the hypothesis that smoking offers protection from developing ulcerative colitis was formulated.

The lower proportion of current smokers among patients compared with the background population agrees with findings in previously published reports. The similar proportion of ex-smokers among patients and controls in our study, however, disagrees with those findings. Perhaps physicians in the 1960s less often advised against smoking than more recently. This would imply that ex-smoking status as a risk factor for ulcerative colitis is not as strong as previously thought. A genetic predisposition to ulcerative colitis and ulcerative proctitis but against cigarette smoking may also explain the differences in smoking habits.

Our result of a higher proportion of patients having symptoms induced by drinking milk after diagnosis compared with controls agrees with that in a study by Wright. In a study by Gilat, however, no such association was found, but the fact that their controls were partly hospital based, sometimes because of different gastrointestinal disorders, could explain their different finding. The increased level of serum antibodies to cow's milk proteins reported among ulcerative colitis patients hints at a biological mechanism.
behind our finding. Lactose intolerance secondary to the ulcerative colitis may also explain this finding.

Most comparisons between non-progressive ulcerative proctitis and extensive ulcerative colitis did not yield any differences. Fathers of extensive colitis patients had a higher socioeconomic status, however, than those of non-progressive ulcerative colitis cases. This finding could explain the different results in different studies analysing parents' socioeconomic status,19 making the assumption that the proportion of extensive ulcerative colitis and non-progressive ulcerative proctitis differ in most studies. Moreover, as in one previous study,20 extensive ulcerative colitis patients were less likely to be current smokers. On the other hand, extensive ulcerative colitis patients were less likely to be exsmokers compared with non-progressive ulcerative proctitis cases. This association could either be explained by smoking as a protective agent against ulcerative colitis or that patients with extensive ulcerative colitis are more likely never to start smoking, conceivably because the disease is systemic and also involves the lungs. Extensive ulcerative colitis patients also seem to have a higher proportion of those having symptoms after drinking milk than non-progressive ulcerative proctitis cases.

Total alcohol consumption did not differ between the two groups and the difference in wine consumption could be caused by chance, as a biological explanation is difficult to formulate. Our finding of an increased number of days in the hospital because of diseases not related to ulcerative colitis is also hard to explain. One feasible explanation could be that when patients with an extensive colitis are hospitalised for any other disease, the treating physician's main concern will still be the colitis, leading to a discharge code for ulcerative colitis.

The findings in our comparison between extensive colitis and non-progressive ulcerative proctitis are not so strong that they confirm the hypothesis of ulcerative proctitis as a specific entity.21 On the other hand, certain differences between the two groups in our study make it premature to classify ulcerative proctitis entirely as a subgroup of ulcerative colitis.21,22
