Comparison of leukocyte excretion and blood loss in inflammatory disease of the bowel

K Teahon, I Bjarnason

Abstract
Clinical relapse of inflammatory bowel disease is characterised by increased neutrophil migration into the intestine. The site of the neutrophil chemoattractant(s), whether luminal or mucosal, may be important since, on contact with a chemoattractant, neutrophils cause indiscriminate damage to their immediate surroundings by generating reactive oxygen species and by lysosomal enzyme release. If this happens within the mucosa, inflammation should correlate significantly with tissue damage as assessed by bleeding, but if it occurs within the intestinal lumen, the inflammation would be disproportionately greater than the bleeding such as is seen in classical exudation. Intestinal inflammation and bleeding were quantitated with the simultaneous use of indium-111 labelled neutrophils (four day faecal excretion of indium-111) and chromium-51 labelled red cells in patients with ulcerative colitis (n=12), Crohn's disease (n=15), and NSAID induced enteropathy (n=34). Intestinal inflammation and blood loss correlated significantly (Spearman) in patients with ulcerative colitis (20-3% v 6-5 ml/d (median) r: 0.85, p<0.001) and NSAID enteropathy (1-6% v 1-9 ml/d, r: 0.60, p<0.01) but not in Crohn's disease (17-0% v 2-1 ml/d, r: 0.38, p>0.1). For a given indium-111 excretion, patients with ulcerative colitis had significantly greater (p<0.01) blood loss than patients with Crohn's disease. These results suggest that the predominant site of neutrophil chemoattractants may be within the mucosa in ulcerative colitis and NSAID enteropathy and within the lumen in Crohn's disease.

(Gut 1993; 34: 1535–1538)

The study of humoral and cellular immunopathogenesis of inflammatory bowel disease has received much interest. The most characteristic feature of clinical relapse is the increased flux of neutrophils into the intestine. Understanding the movement of neutrophils and the mechanisms through which they mediate tissue injury is fundamental to elucidating the pathogenesis of relapse.

Although controversial, it now seems likely that the striking 'in vitro' findings of reduced neutrophil mobilisation and altered function in patients with inflammatory bowel disease are not intrinsic to the cell but reflect neutrophil conditioning by different inflammatory milieu. Study of indium-111 labelled neutrophils shows close similarities between ulcerative colitis and Crohn's disease in respect of the quantity and kinetics of neutrophil migration from blood to lumen across the intestinal mucosa. The question then arises as to the site and nature of the neutrophil chemoattractant. The latter has been extensively studied by Stenson, who suggested a two stage pathogenic framework for inflammatory bowel disease. He proposes that there is an as yet unknown triggering event which initiates an early neutrophil influx. Subsequent to this there is an amplified second phase of neutrophil chemotaxis which is much greater than the original. There is compelling evidence to suggest that the second amplification stage is mediated by leukotriene B4, a lipo-oxygenase product released by the neutrophils themselves.

It is clear that whatever the primary or secondary chemoattractant is the neutrophils destined for it will respond in a predictable fashion. On contact with the chemoattractant they form oxygen reactive species and there is release of lysosomal enzymes after phagocytosis. Both of these mechanisms may destroy the chemoattractant but will also cause unavoidable nonspecific damage in the immediate vicinity of the neutrophil.

The site of neutrophil chemoattractants may therefore be an important determinant of the secondary damage (as assessed by blood or protein loss) caused by neutrophils. This is particularly well demonstrated in the experimental animal where the emigration of neutrophils through the intestinal mucosa in response to a luminal chemoattractant does not cause tissue damage while intra-cutaneous inoculation of the same substance does.

In an attempt to localise, in vivo, the site of neutrophil chemoattractants in patients with ulcerative colitis and Crohn's disease, we used a dual isotope method to quantitate simultaneously intestinal inflammation and blood loss. We argued from the above that the two should correlate closely if the neutrophils are seeking a mucosal chemoattractant, less so if the chemoattractant is in the lumen, in which case the inflammation should be disproportionately greater than the blood loss. Patients on non-steroidal anti-inflammatory drugs (NSAID) acted as a control group. There is some evidence to suggest that the neutrophil chemoattractant in NSAID enteropathy may be a metronidazole sensitive microbe.

Subjects and methods
Patients were recruited from gastroenterology and rheumatology outpatient clinics at Northwick Park Hospital. All patients gave fully informed consent to the studies which were approved by the Harrow Health Authority Ethical Committee.
INFLAMMATORY BOWEL DISEASE

Twelve patients with ulcerative colitis (eight pancolitis and four left sided colitis; age 22–70 years; five were on sulphasalazine and two on prednisolone 10 and 30 mg) and 15 patients with Crohn’s disease (one of whom had undergone ileal resection) (six ileal and pancolitis, one left sided colitis, six ileal and two small intestinal; age 18–70 years; 13 were on no treatment, one on 10 mg prednisolone and one on sulphasalazine) were studied. There were no significant differences in haemoglobin; white cell and platelet counts; erythrocyte sedimentation rate; or clinical disease activity between patients with ulcerative colitis and those with Crohn’s disease. After the indium-111 and 51-chromium excretion studies all patients had a full colonoscopy or double contrast barium enema to confirm the diagnosis and to evaluate the extent of disease.

PATIENTS WITH RHEUMATOID ARTHRITIS

Thirty four patients with rheumatoid arthritis were studied. The patients had been on treatment for more than six months and although the type of NSAID varied, all had been established on one drug continuously for over six weeks. Twenty patients were on concomitant, second line agents (nine colchicine, six gold im, five penicillamine); but we have previously shown that these drugs do not affect the frequency or severity of the small intestinal inflammation caused by NSAIDs.17 18

INDIUM LABELLING STUDIES

An indwelling catheter was placed in an antecubital vein. Six millilitres of blood were drawn into a syringe containing 11 ml of acid citrate dextrose (National Institutes of Health formula A), dispensed into two sterile polyethylene tubes, and allowed to sediment for one hour at room temperature. The supernatent was removed and centrifuged at 100 g for five minutes. The resultant supernatent was removed immediately and respun at 300 g to yield a cell free plasma. The pellet from the 100 g centrifugation was resuspended and incubated for 10 minutes at room temperature in 0-1 HEPES saline buffer (pH 7-4) containing 20 mM HEPES in 0-8% sodium chloride, 4-4 mM tropolone and 300 μCi (11 MBq) indium-111 chloride (Amersham International). Five millilitres of cell free plasma were added to the cell suspension and centrifuged at 100 g for five minutes. The suspension containing the unlabelled indium-111 was poured off and the labelled cells were resuspended in 6 ml of cell-free plasma. Five millilitres (7–9 MBq) were injected and the rest used for standards. The labelling efficiency by this technique averages 84% (range 74–93%).14 The leukocytes maintain their integrity and function during this procedure.3

Abdominal scintigrams were obtained at one to four hours and 20 hours after injection of the labelled cells, to localise the site and extent of disease using an IGE 400 AT gamma camera with a STAR computer at the appropriate channel settings.

Individual faecal excretions were collected over a four day period in 500 ml polythene clip top containers. Standards (0-1 ml aliquots of the labelled cells) were made up to 50 ml with water and distributed over a fixed amount of filter paper in an identical container. Both samples and standard were individually counted in a high resolution bulk sample counter as previously described.21 Counts were made for 20 seconds, which allows the measurement of 0-01% of the injected dose with a counting accuracy of ±4%. Each count was then corrected for any chromium-51 crossover into the indium-111 channel which is negligible if performed at completion of the study. Normal excretion values had been obtained in patients with the irritable bowel syndrome (n=14) who excreted 0-5% (mean) with an upper limit of normal at 1%.

BLOOD LOSS STUDIES

At the same time as blood was obtained for leukocyte labelling, 10 ml were dispensed into 40 ml of citrate-phosphate-dextrose solution containing trisodium citrate dihydrate 3 (w/v), sodium dihydrogen phosphate 0-015 (w/v), dextrose 0-2 (w/v) at pH of 6-9. The solution was centrifuged at 1000 g for 10 minutes, the supernatant was discarded and 1-5 μCi/kg body weight of disodium (51) chromate was added dropwise to the pellet of red cells while mixing gently. The pellet was allowed to stand at room temperature for 15 minutes to allow binding to occur and unbound 51-chromium was then removed by washing with 0.9% saline. The final pellet was made up to 10 ml with saline before injection into the patient.

Individual faecal excretions were made for five days in conjunction with the indium-111 neurophil studies. Standards were made up by drawing 5 ml of venous blood daily for four days after injection of the labelled red cells. Four ml were distributed over a fixed amount of filter paper in a faecal collection container. Once the indium-111 counting was completed the samples were stored for four to six weeks to allow decay of the indium-111. Each count was corrected for any possible spillover of residual indium-111. The chromium-51 activity in the stools was correlated with the chromium-51 activity in blood from the previous day which allows quantitation of intestinal blood loss. The upper normal limit of intestinal blood loss is 1-0 ml/day. Using a 300 μCi (11 MBq) injection of indium-111 and a 100 μCi (4 MBq) injection of chromium-51 the estimated radiation dose received by the patient during these studies is 7-2 mili Sieverts (effective dose equivalent).

STATISTICAL ANALYSIS

Wilcoxon’s rank sum test was used for non-parametric data to analyse the mean values, which are given as median and interquartile range. Spearman’s rank correlation coefficient was used to correlate between inflammation and bleeding. The sign test was used to assess the differences in red cell loss (using the square root data) between patients with ulcerative colitis and those with Crohn’s disease for a given level of inflammation.

**Results**

The Table shows that there was no significant difference in the four day faecal excretion of indium-111 between patients with ulcerative colitis or Crohn’s disease. Figure 1 shows that there is a significant correlation between the inflammation and blood loss in patients with ulcerative colitis (r = 0.85, p<0.002) but not in those with Crohn’s disease (r = 0.38, p>0.1). At a given faecal excretion of indium-111 (% dose) patients with ulcerative colitis have significantly greater blood loss (p<0.001) than patients with Crohn’s disease.

When patients with small and large bowel Crohn’s disease were analysed separately there was no significant difference between the faecal excretion of indium-111 leukocytes and chromium 51 red cells, and the lack of significant correlation between the two parameters was evident in both subgroups (small bowel Crohn’s (r = -0.08, p=0.80) and large bowel Crohn’s (r=0.39, p=0.30)). Moreover, for a given faecal excretion of indium-111, patients with both small and large bowel Crohn’s disease bleed significantly (p<0.02) less than patients with ulcerative colitis.

The Table shows that patients on NSAIDs had significantly less inflammation than patients with inflammatory bowel disease but the blood loss was similar to that of patients with Crohn’s disease. Figure 2 shows that there is a significant correlation (r=0.60, p<0.001) between inflammation and blood loss in patients taking NSAIDs.

**Discussion**

The techniques of indium-111 labelled neutrophils and chromium-51 red cells are well described and are accurate, specific, and sensitive methods for quantitating intestinal inflammation and blood loss. The indium-111 leukocyte technique is particularly suitable for the present study since it utilises the homing properties of neutrophils in response to specific chemoattractants. Its simultaneous use with labelled red cells shows the specificity of the technique and the selectivity of neutrophil migration to the intestine in these disorders.

Thus, as neutrophils are normal constituents of blood it would seem possible that the faecal excretion of indium-111 simply reflected non-specific intestinal bleeding or oozing (for example, vascular injury due to eroding ulcers). If this was indeed the case, then each 1% of injected neutrophils excreted in faeces should be associated with equivalent blood loss. However, 1% of the circulating blood volume in an average person (five litres) is 50 ml. Clearly, the excretion of the neutrophils is considerably greater than could be accounted for simply by bleeding. Of the various neutrophil functions – namely adherence, aggregation, orientation, locomotion, and chemotaxis – few are better defined and understood than the sequence of events when the neutrophil comes into contact with a chemotactant.

On contact free radical species are generated via nicotinamide adenine dinucleotide phosphate linked oxidase, flavoproteins, cytochrome b, and myeloperoxidase. Comminating phagocytes internalise the chemotactant for further degradation with subsequent lysosomal enzyme release. Both neutrophil and eosinophil, however, cause indiscriminate damage in the immediate vicinity to the neutrophil. The idea that damage relates to the localisation of the chemoattractant, whether mucosal or luminal, is supported by data in the experimental animal.

Although the pathogenesis of the three disorders is uncertain, that of NSAID enteropathy is probably best understood. NSAIDs cause direct cellular damage during drug absorption by several interacting actions on intermediary metabolism. The mucosa is further compromised because of the effect of NSAIDs on cyclo-oxygenase, effectively preventing the production of reparative prostaglandins. Damaged intercellular junctions allow increased permeation of luminal substances, which by itself seems to be insufficient to elicit detectable neutrophil chemoattraction. Indeed inflammation is only consistently evident after six months of NSAID ingestion and may be due to a metronidazole sensitive microbe. The driving force for inflammation then is a combination of drug and luminal induced mucosal damage. Although not directly comparable (because of the different range of indium-111 faecal excretion) it seems that there is similar blood loss in NSAID treated patients and patients with Crohn’s disease, although the inflammatory activity was 10 fold higher in the...
latter. Combined with the rather weak correlation between inflammation and bleeding (r = 0.60) this suggests that most of the neutrophils are seeking a mucosal signal, some may also be destined for the lumen in NSAID induced enteropathy.

In inflammatory bowel disease the initial or predisposing event is unknown. The relapse, however, may be due to a chemoattractant with secondary amplification by local neutrophil leukotriene production and it is of note that twice as many leukotrienes are found in ulcerative colitis mucosa than in Crohn’s disease.1,2 The different results obtained in this study in patients with ulcerative colitis and Crohn’s disease agrees with many clinical and experimental observations. It confirms the clinical dictum that patients with ulcerative colitis often present with a greater degree of blood loss than patients with Crohn’s disease, and that this is not simply a matter of being concealed (or occult) in Crohn’s disease. The data are consistent with detailed histopathological assessment showing that the mucosal neutrophils in ulcerative colitis are activated and show ultrastructural evidence of phagocytosis and granular extrusion. In Crohn’s disease, however, where the mononuclear cell infiltrate is both transmural and patchy, the neutrophils are mainly centred around ulcers and show little evidence of the activation that occurs on contact with a chemoattractant. The prominence of a luminal neutrophil chemoattractant in active Crohn’s disease may partly explain the observation that treatments directed towards altering the luminal milieu (elemental diets, total parenteral nutrition, and diversion surgery) are consistently as effective for active Crohn’s disease as they are ineffective for patients with ulcerative colitis.3,4 Luminal factors also seem to be important in the recurrence of disease after surgery.3,5 The precise nature of neutrophil chemoattractants in these disorders is unknown and there could be of a diverse nature including microbial, chemical (including prostanooids) or indeed in ulcerative colitis the damaged colonicocytes themselves.

In conclusion, the acute inflammatory infiltrate and bleeding go hand in hand in active ulcerative colitis and in patients taking NSAIDs, suggesting that the main neutrophil chemoattractant is within the mucosa. In Crohn’s disease there is disproportionately greater inflammation than blood loss and the lack of correlation between the two suggests that the predominant site of the chemoattractants is within the gut lumen.

Thanks to Drs M J Gumpel and A J L Levis for allowing us to study patients attending their outpatient clinic.
