Gastric secretion of platelet activating factor and precursors in healthy humans: effect of pentagastrin

I Sobhani, Y Denizot, S Hochlauf, D Rigaud, J Vatier, J Benveniste, M J Lewin, M Mignon

Abstract
The release of platelet activating factor (PAF-ACETHER or PAF) and its precursors in the gastric lumen was assessed in 13 normal subjects in basal condition and after stimulation by gastrin. Acid, peptic, and sialic acid outputs were determined under the same conditions. Gastric juice was collected using a nasogastric tube after overnight fast in basal condition for 60 minutes, then under pentagastrin infusion (6 μg/kg/hr for 60 minutes). Platelet activating factor was detected at low concentration in 4/13 subjects under basal condition (mean (SEM) 1.2 (0.6) pg/hr) while high concentrations of lyso platelet activating factor (6.1 (1-8) μg/hr) and of alkyl-acyl-glycerophosphocholine (AAGPC) (11.5 (3) μg/hr) were found in 13 and 11 subjects, respectively. Platelet activating factor was not detected during pentagastrin infusion, while lyso platelet activating factor and alkyl-acyl-glycerophosphocholine were detected in 13 and in 12 subjects, respectively. Compared with the basal condition these platelet activating factor precursors increased significantly (p<0.001) going up to fivefold baseline (31.8 (6-8) μg/hr and 53 (9-3) μg/hr respectively) in response to pentagastrin. There was a positive correlation between platelet activating factor precursors and acid or peptic output but not between platelet activating factor precursors and sialic acid. As sialic acid may be considered an index of mucus glycoprotein degradation, it seems that gastrin stimulation of gastric epithelial cells results in a concomitant secretion of platelet activating factor precursors, acid, and peptic irrespective of mucus glycoprotein degradation.

Patients and methods
SUBJECTS
Thirteen male volunteers (ages ranging from 20 to 53, mean 29 years) were investigated. They had no previous medical history of gastrointestinal, inflammatory, hypersensitivity, or neoplastic diseases, and none was taking drugs; two of 13 were smokers (subjects 3 and 6, Table). All individuals gave informed consent and had gastric juice analysis: after an overnight fast, a nasogastric tube was positioned in the gastric antrum with endoscopy guidance and its correct position checked by the water recovery test with the subjects in semirecumbent position. The gastric juice was collected by gentle manual aspiration during 135 minutes. The first 15 minute sample was discarded. Then basal samples were collected every 15 minutes for one hour followed by four 15 minute samples collected during intravenous infusion of pentagastrin (6 μg/kg/hr). Each sample was submitted to assay for platelet activating factor, platelet activating factor precursors, acid, peptic, choline, and N-acetylneuraminic acid (NANA).

Measurement of platelet activating factor and precursors
For extraction of platelet activating factor and platelet activating factor precursors, gastric juice samples were immediately mixed on ice with 100% ethanol (1 vol:4 vol) and kept at −20°C until platelet activating factor assay. Platelet activating factor concentration was measured in

*Mean value of four 15 minute concentrations; Vol: volume as sum of four 15 minute gastric liquid aspirated; B: basal condition; PG: pentagastrin infusion; AAGPC: alkyl-acyl glycerophosphocholine; Student’s paired test with significance set at p<0.05, was used.

Each 15 minute sample, then lyso platelet activating factor was assessed after chemical acetylation and AAGPC after alkaline hydrolysis and subsequent acetylation.

Platelet activating factor extraction and purification – Gastric juice lipids were extracted using 80% ethanol. These ethanol extracted samples were dried. For high performance liquid chromatography (HPLC) analysis, the dried residues were dissolved in 500 μl of solution comprising 60:50:5 dichloromethane/methanol/water (vol:vol). Samples were then applied to a Microporasil column 3·9 mm ID, 300 mm length (Waters Associates, Milford, MA, USA) with a flow rate of 1 ml/min. Each 1 ml fraction was dried and resuspended in 50 μl of 60% ethanol and then assayed for platelet aggregating activity.

Assay for platelet activating factor – Washed rabbit platelets were prepared as previously described. Aspirinized platelets (1·6·10⁶) in 300 μl of Tyrode’s solution, containing 2·5% gelatin and the adenosyl diphosphate (ADP) scavenger mixture creatine phosphate (1 mM) and creatine phosphokinase (10 U/ml) were stirred in an aggregometer (Icare, Marseille, France). Aggregating activity of the samples was measured over the linear portion of the calibration curve obtained with synthetic platelet activating factor.

Assay for lyso platelet activating factor – Lyso platelet activating factor was measured after chemical acetylation into platelet activating factor. Briefly, the ethanolic extracts were dried under an air stream, mixed with 200 μl of pyridine and acetic anhydride and kept for 18 hours in the dark, at room temperature. Samples were evaporated and traces of pyridine were removed with dichloromethane. Samples were recovered with 100 μl of 60% ethanol and were assayed as described above. The amount of lyso platelet activating factor was calculated as the difference between the quantity of platelet activating factor measured after and before acetylation of the samples.

Assays for AAGPC – AAGPC were measured after alkaline hydrolysis and subsequent acetylation. Briefly, aliquots of the dried extracts were treated with 0·03 N NaOH in methanol for 2 hours at room temperature. The pH was adjusted to 7·0 with 1 N HCl and the mixture was evaporated to dryness. The amount of AAGPC was calculated as the difference between the concentrations of platelet activating factor measured after and before alkaline hydrolysis and acetylation.

Characterisation of platelet activating factor – In addition to its ADP and arachidonic acid independent aggregating activity on rabbit platelets, the lipidic material extracted from gastric juice samples was pooled, dried, and eluted on HPLC. The platelet aggregation activity was eluted from 18 to 21 minutes. This material had a retention time typical of platelet activating factor during HPLC analysis using phosphatidylcholine, lysophosphatidylcholine, and synthetic platelet activating factor as standards and was further characterised as platelet activating factor on the basis of the following criteria: (a) its aggregating activity was suppressed in the presence of 0·1 mM BN 52021, a specific platelet activating factor receptor antagonist; (b) and after incubation of the samples with 10 μg/ml phospholipase A₂ from hog pancreas; lipase A₁ from R arrhizus 100 μg/ml was without effect. The efficiency of this procedure averaged 80% using (H) platelet activating factor as internal standard.

GASTRIC ACID MEASUREMENT

Gastric acid was measured by automated titration using 1/10 N NaOH to an endpoint of pH 7·0 and determined as mmol/l.

CHOLINE MEASUREMENT

Choline concentration in gastric juice was used as duodenogastric bile reflux marker. We have previously reported that measurement of choline is sufficient to exclude bilipancreatic reflux in the stomach when its amount is below 10 μmol/hr. The concentration of choline in gastric juice was measured by an enzymatic method as described: phospholipase D treatment and oxidation by 4-aminoazobenzene (Biolyon).
Gastric secretion of platelet activating factor and precursors in healthy humans: effect of pentagastrin

**Pepsin measurement**

The proteolytic activity of each 15 minute gastric juice samples was determined by an automatic method using human haemoglobin as substrate\(^1\) and the concentration was determined as UP/ml.

**Sialic acid determination**

N-Acetyleuraminic acid (NANA), a sialic acid linked to mucus glycoproteins, was determined according to Aminoff.\(^2\) Briefly, NANA was oxidised by periodic acid (0.9 N; 37°C), and then this oxidised component was bound to thiobarbituric acid giving a stable chromophore in butanol. The adsorption was read at 549 nm and compared with a scale of the NANA standard. The results were expressed in μg/ml. The concentration of solubilised NANA in gastric juice was obtained by the difference between total NANA measured after acidic hydrolysis (H₂SO₄ 0.1 N, 80°C, 60 min) and free NANA measured directly as μg/ml.\(^2\)

**Calculations and statistical tests**

Volume of total gastric juice in basal and under pentagastrin infusion was calculated as the sum of four 15 minute samples in each period (Table) and the hourly output of each substance (platelet activating factor: pg/hr; lyso platelet activating factor: μg/hr; AAGPC: μg/hr; acid: mmol/hr; pepsin: pepsin unit UP/hr; NANA: μg/hr; choline: μg/hr) was calculated as the sum of four 15 minute rates of secretion; each 15 minute rate having been determined by multiplication of concentration by the volume of gastric juice aspirated during 15 minutes. All values were expressed as mean (SEM). Statistical analysis were performed with the Student’s paired t test, and the Spearman rank correlation tests. To show the concentration pattern in basal and under pentagastrin conditions, we also calculated concentrations of acid, platelet activating factor, platelet activating factor precursors, and NANA as the mean of four 15 minute concentrations for each period, basal and pentagastrin (Table).

**Results**

Mean concentrations of platelet activating factor and precursors in gastric juice in basal condition and during pentagastrin infusion are shown in the Table. In the basal condition as well as under pentagastrin infusion choline outputs remained below 10 μmol/h (mean = 1.5 (0.8) and 4 (2) μmol/h, respectively), so that no subject had to be excluded because of duodenogastric bile reflux.

**Gastric platelet activating factor precursors in basal condition and under pentagastrin**

Lyso platelet activating factor – It was detected in all subjects with amounts ranging from 1 to 23 μg/h (mean 6.1 (1.8)) in basal condition and increased significantly (1 to 77 μg/h; mean 31.8 (6.8) μg/hr) under pentagastrin infusion (Table and Fig 1).

AAGPC – It was detected in 11 of 13 subjects with amounts ranging from 2 to 35 μg/h (mean 11.5 (3)) in basal condition and increased significantly (10 to 109 μg/h; mean 53 (9.3)) under pentagastrin infusion (Table and Fig 1). Overall, in a given subject, the platelet activating factor and precursors concentrations determined in each 15 minute samples were very close to those obtained from hourly pooled gastric juice.

**Gastric platelet activating factor in basal condition and under pentagastrin**

Platelet activating factor was detected in four of 13 subjects (30%) in all 15 minute gastric juice samples; hourly amounts ranged from 1 to 8 pg/h (mean 1.2 (0.6)). In the remaining subjects platelet activating factor was not detected in any 15 minute sample or in hourly pooled gastric juice samples. Platelet activating factor was not detected under pentagastrin infusion in any 15 minute sample or in hourly pooled gastric juice; thus, compared with the basal situation, its secretion decreased in four subjects (Fig 1).

---

*Figure 1: Individual hourly gastric output values of acid, platelet activating factor (PAF), PAF precursors, pepsin, and N-acetylneuraminic acid (NANA) are indicated in basal (B) condition and in response to pentagastrin (PG) in healthy volunteers; solid line designates the median. The Student's t paired test was used for the comparison between basal and pentagastrin period.*
CORRELATION BETWEEN PLATELET ACTIVATING FACTOR PRECURSORS AND ACID, PEPsin, AND NANA

As expected basal acid, pepsin, and NANA outputs (3-2 (0-7) mmol/h, 283 (53) UP/h, and 1100 (140) µg/h, respectively) increased significantly under pentagastrin infusion (28 (2-5) mmol/h, 985 (145) UP/h, and 1763 (292) µg/h), respectively; Fig 1.

Under pentagastrin stimulation, taking all subjects together, the regression analysis showed a significant correlation between lyso platelet activating factor and acid, lyso platelet activating factor and pepsin, AAGPC and acid, AAGPC and pepsin (Fig 2). When hourly gastric outputs were compared, no significant correlation was found between NANA and lyso platelet activating factor (r=0-08; p=0-6), NANA, and AAGPC (r=0-45; p=0-06); again, when concentrations were compared no significant correlation was found between NANA (µg/ml) and lyso platelet activating factor (ng/ml) (r=0-4; p=0-19) or NANA and AAGPC (µg/ml) (r=0-05; p=0-86).

Discussion

In this study, we showed that in healthy volunteers, secretion of gastric platelet activating factor precursors increased under pentagastrin infusion. We found a relation between platelet activating factor precursors and acid, and between platelet activating factor precursors and pepsin.

Given the various substances that can activate platelets, it was necessary to show that the platelet aggregating material purified from gastric juice samples was platelet activating factor. To do this, we used experimental criteria to characterise and distinguish it from arachidonic acid, prostaglandin, cholin, thrombin, or adenosine diphosphate (see Methods). Yet, choline output remained below 10 µg/h showing that lipid material purified from gastric juice was not of bilipancreatic origin. In this study, we preferred choline measurement to a duodenal or pyloric occluding balloon that might induce gastric or duodenal distension.

Platelet activating factor is one of the most potent lipid mediators discovered, which exerts a wide span of cellular and tissue effects ranging from degranulation of inflammatory cells to mucosal ulceration and necrosis. Platelet activating factor plays a part in the mucosal injury of the gastrointestinal tract in animals. In humans, platelet activating factor has been found in patients with oesophagitis, ulcer gastric, Crohn's disease, and ulcerative colitis by us and others. Until now, however, only a few data pointed to the production of platelet activating factor in physiological processes. In this study, we found platelet activating factor in four of 13 normal subjects. The concentration of platelet activating factor in this study (1-2 pg/h) is much lower than that we had previously found in patients suffering from oesophagitis (28 pg/h), erosive gastritis (25 pg/h), and duodenal ulcer (5 pg/h). The significance of platelet activating factor in the gastric juice of healthy humans is still difficult to analyse. In this study, all subjects were selected on the basis of standard criteria of normality. We can not exclude the possibility, however, of abnormal metabolism of platelet activating factor in four of them. Two of four were smokers (patients 3 and 6) suggesting a possible cause of abnormal platelet activating factor metabolism; yet, non-symptomatic
Gastric secretion of platelet activating factor and precursors in healthy humans: effect of pentagastrin

Gastritis related to Helicobacter pylori (H. pylori) cannot be excluded in them (or at least, in two non-smokers). Nevertheless, in our previous study performed in 36 symptomatic patients, we showed that neither the concentration of gastric platelet activating factor output or the content of platelet activating factor in the gastric mucosa were significantly related to the inflammatory cell infiltration in the gastric mucosa.\(^\text{11}\) Clearly, whether low gastric platelet activating factor concentration in 36 normal settings should be considered as physiological or pathophysiological needs further investigation. H. pylori, which is able to generate in vitro platelet activating factor from platelet activating factor precursors,\(^\text{12}\) may be a possible pathophysiological cause of platelet activating factor increase. More than 90% of patients with duodenal ulcer are carriers of H. pylori. All carriers of the bacterium, however, do not suffer from duodenal ulcer. Thus, the role of platelet activating factor should be interpreted considering both H. pylori and acid.

The fact that pentagastrin increased platelet activating factor precursors would suggest that platelet activating factor may have a role in the gastric functions, in particular gastric acid secretion. A possible relation between platelet activating factor and gastric acid secretion\(^\text{12-13}\) and platelet activating factor and gastric motility\(^\text{14}\) has already been suggested as a physiological phenomenon in the gastrointestinal tract. Also Wallace and Keenan\(^\text{14}\) have reported that intraluminal administration of platelet activating factor may have a protective role in the gastrointestinal tract in animals.

As platelet activating factor was not detected under pentagastrin infusion, two hypotheses should be discussed concerning the effect of pentagastrin on gastric platelet activating factor synthesis. Firstly, gastrin would exert a direct negative effect on platelet activating factor synthesis. Such a mechanism seems unlikely because platelet activating factor precursors increase under pentagastrin infusion. Alternatively, gastrin might affect enzymes participating in platelet activating factor generation by acid or pepisin. Benveniste et al.\(^\text{15}\) showed that platelet activating factor was susceptible to lipase C and D,\(^\text{15}\) and Moreau et al.\(^\text{15}\) reported that pentagastrin could enhance gastric lipase activity in humans. This hypothesis deserves further study as platelet activating factor metabolism in the stomach lumen is unknown. In our previous study of gastric platelet activating factor analysis, gastric juice content seemed to be a more valuable index than mucosal content as platelet activating factor was not detectable in several biopsy specimens. This might be as a result of the weight of endoscopy biopsy samples. The ratio of platelet activating factor/lyso platelet activating factor/AAGPC in the gastric mucosa was similar to that of gastric juice. For all these reasons, we think that extraction of platelet activating factor and precursors from the gastric mucosa would not give more information than that obtained from gastric juice analyses. Yet, in this study the amount of platelet activating factor (0-09 ng/ml; 1-2 ng/h) is much lower than that of lyso platelet activating factor (0-09 ng/ml; 0-1 ng/h) and AAGPC (0-14 µg/ml; 11-5 µg/h) suggesting that platelet activating factor degradation may not be the only source of platelet activating factor precursors under pentagastrin stimulation. Because calcium is increased in gastric epithelial cells\(^\text{4}\) in response to gastrin and the remodelling pathway of platelet activating factor synthesis is activated by calcium,\(^\text{10}\) platelet activating factor precursors seem to be related to the calcium content of gastric cells.

Acid and pepisin are released from gastric epithelial cells. NANA, which represents the sialic acid linked to mucus glycoproteins,\(^\text{10}\) illustrates glycoprotein erosion under pentagastrin stimulation.\(^\text{2}\) As the regression analysis showed a significant correlation between platelet activating factor precursors and both acid and pepticin but no significant correlation between platelet activating factor precursors and NANA, we suggest that platelet activating factor precursors would not result from degraded gastric mucin. In conclusion, the rise in platelet activating factor precursors induced by pentagastrin correlates with acid and pepisin. This correlation argues for the possibility of synthesis of platelet activating factor precursors in cells sensitive to gastric acid stimulation.

17 Caxenave JP, Benveniste J, Mustard FJ. Aggregation of rabbit platelets by platelet-activating factor is independent of the release reaction and the arachidonate pathway and inhibited by membrane-active drugs. Lab Invest 1979; 41: 275-85.
