Abstract
Changes in biliary lipid composition, pH, ionised calcium, total and unconjugated bilirubin, and cholesterol nucleation time of gall bladder bile samples were examined in six patients who had undergone subtotal or total colectomy between five months and seven years previously, and values were compared with those in control patients with no gall stones. The colectomy group mainly comprised patients with ulcerative colitis and familial adenomatosis coli, in whom only a short length of the terminal ileum (mean (SEM) 2.25 (0.57) cm) had been resected. The reconstruction procedures were ileoanal anastomosis in two patients, terminal ileostomy in two, ileorectal anastomosis in one, and J shaped ileal pouch-anal anastomosis in one patient. The distributions of age, sex, and relative body weight were similar in the two groups. The gall bladder bile was similar in the two groups. The patients in whom these procedures were performed - these patients had a significantly increased cholesterol saturation index (p<0.01) and rapid cholesterol nucleation time (p<0.05) compared with the control group. A significant increase in the molar percentage of cholesterol and a decrease in that of total bile acid associated with significantly decreased secondary bile acids (p<0.05) were observed in the post colectomy group. Gall stones formed in two of six patients after colectomy were cholesterol stones containing more than 80% cholesterol by dry weight. Total and unconjugated bilirubin, pH, and ionised calcium values were similar in the two groups. The results indicate that after total or subtotal colectomy the composition of gall bladder bile increases the risk of cholesterol gall stone formation.

Methods

PATIENTS
Post colectomy group
Six patients who had undergone elective colectomy participated in the study (Table 1). There were four women and two men with a mean (SEM) age of 41.8 (7.4) years. Total colectomy had been performed in three patients and subtotal colectomy in the remainder. The mean (range) time since colectomy was 3–7 years (5 months to 7 years). Three patients had ulcerative colitis, two familial adenomatosis coli, and one patient had multiple colonic ulcer. In all six patients only very short lengths of the terminal ileum (less than 5 cm, mean (SEM) 2.25 (0.57) cm) were resected. Reconstruction procedures after colectomy were ileoanal anastomosis in two;

*Significantly different from the control (p<0.01).

ileostomy in two, ileorectal anastomosis in one; and J shaped ileal pouch-anal anastomosis in one patient. None of the patients had gall bladder disease at the time of colecotomy; this had been confirmed by preoperative ultrasonography and intraoperative palpation of the gall bladder. Two of the six patients (patients 1 and 2) developed gall stone disease four months and 57 months respectively after colecotomy and another patient (patient 5) had gall bladder sludge five months after colecotomy (Table I). These patients underwent cholecystectomy. The other three patients underwent a second operation for closure of ileostomy with ileoanal anastomosis (patient 3), resection of minor ileoenteric fistula after subtotal colecotomy with ileorectal anastomosis (patient 4), and resection of duodenal tumour (patient 6).

Gall stone free control group
This group consisted of six men and five women with a mean (SEM) age of 54.6 (4.0) years. There were four patients with colon cancer, four with gastric cancer, two with pancreatic cancer, and one with pheochromocytoma of the adrenal gland. The absence of gall stone disease was confirmed by preoperative ultrasonography and intraoperative palpation of the gall bladder.

All the patients studied were eating a normal diet. They had no diseases affecting the hepatobiliary system and their liver function tests were within the normal range. No significant differences were found in age, sex, and the relative body weight (colecotomy v control, 97.9% v 88.2%) between the two groups. Informed consent was obtained from all patients before surgery. The study was approved by the senior committee of the department.

BILE SAMPLES
At the time of surgery and after an overnight fast, gall bladder bile was completely aspirated by needle to avoid stratification of bile, and care was taken to avoid contamination with blood. Fresh gall bladder bile samples thus obtained were kept in sterile test tubes at 37°C in the dark and were immediately subjected to determinations of pH, ionised calcium, and total and free bilirubin. Bile samples (3 ml) were ultracentrifuged at 37°C for two hours at 105 g (55 P-72, Hitachi, Tokyo, Japan) and the isotropic bile samples obtained for the nucleation study as described below. Part of the bile sample was stored at –20°C for chemical analyses.

BILE ANALYSIS
The ionised calcium and pH of fresh gall bladder bile were determined using an automated analyser (CAI 101, Shimadzu, Kyoto, Japan). Concentrations of individual bile acids and cholesterol were simultaneously determined using gas-liquid chromatography (GC 15 A, Shimadzu, Kyoto, Japan, equipped with a fused silica column – HiCap-CB8P1, 20 m×0.2 mm ID, Shimadzu, Kyoto, Japan) as previously reported.9 The total bile acid concentration was determined as the sum of the individual bile acids. Phospholipid was quantitated by the method of Bartlett.10 The cholesterol saturation index was calculated according to the critical table provided by Carey.11 Total bilirubin was determined as described by Michaelsson12 and the bilirubin fractions were analysed using high performance liquid chromatography (ALC/ GP C 202, Waters, Milford, MA) according to the method of Spivak and Carey.13

Gall stone analysis
Gall stones obtained from two patients who had undergone colecotomy were dried, weighed, crushed, and extracted with dimethylsulphoxide-acetone-1 N HCl (90:9:1 v/v/v) and were subjected to the determination of cholesterol as previously reported.14

NUCLEATION TIME
The earliest time that cholesterol monohydrate crystals appeared in gall bladder bile was determined as previously described.7,8,15 based on the method of Holan et al.16 After confirming the absence of cholesterol monohydrate crystals, isotropic bile samples were kept in sterile brown tubes under nitrogen at
The method.

The inhibition was subsequently observed by Makino, Chijiiwa, Higashijima, Nakahara, Kishinaka, Kuroki, and Mibu in 1994. In the context of nucleation in bile, the concentration of biliary cholesterol was higher in the colectomy group than in the controls, although the difference was not statistically significant. The molar percentage of cholesterol, however, was significantly higher in the colectomy group. The total bile acid concentration was lower in the colectomy group but this was not statistically significant. The molar percentage of total bile acid was significantly decreased in the colectomy group. The molar percentage of phospholipid was significantly higher in the colectomy group. The ionised calcium, pH, and total bilirubin concentration were similar in the two groups. The proportion of unconjugated bilirubin was higher in the colectomy group than the controls, but there was no statistically significant difference.

The gall bladder bile acid composition is shown in Table III. The cholic acid level was significantly higher (p<0.01) and the deoxycholic acid value was significantly lower (p<0.05) in the colectomy group. The molar percentage of chenodeoxycholic acid was similar in the two groups. The sum of cholic acid plus its metabolite (deoxycholic acid) and that of chenodeoxycholic acid plus its metabolites (lithocholic acid and ursodeoxycholic acid) were not significantly different between the two groups. Primary bile acid was significantly higher in the controls (p<0.01). Secondary bile acids were absent or only present as traces in the colectomy group.

**Results**

**GALLBLADDER BILE COMPOSITION**
The biliary lipid composition and cholesterol saturation index are shown in Table II. The cholesterol saturation index of the gall bladder bile in the colectomy group was significantly higher than that in the gall stone free control group (p<0.01). The total lipid concentration was similar in the two groups. The concentration of biliary cholesterol was higher in the colectomy group than in the controls, although the difference was not statistically significant. The molar percentage of cholesterol, however, was significantly higher (p<0.01) in the colectomy group. The total bile acid concentration was lower in the colectomy group but this was not statistically significant. The molar percentage of total bile acid was significantly decreased in the colectomy group. The molar percentage of phospholipid was significantly higher in the colectomy group. The ionised calcium, pH, and total bilirubin concentration were similar in the two groups. The proportion of unconjugated bilirubin was higher in the colectomy group than the controls, but there was no statistically significant difference.

The gall bladder bile acid composition is shown in Table III. The cholic acid level was significantly higher (p<0.01) and the deoxycholic acid value was significantly lower (p<0.05) in the colectomy group. The molar percentage of chenodeoxycholic acid was similar in the two groups. The sum of cholic acid plus its metabolite (deoxycholic acid) and that of chenodeoxycholic acid plus its metabolites (lithocholic acid and ursodeoxycholic acid) were not significantly different between the two groups. Primary bile acid was significantly higher in the controls (p<0.01). Secondary bile acids were absent or only present as traces in the colectomy group.

**CHOLESTEROL SATURATION INDEX AND TIME AFTER COLECTOMY (FIG 1)**
An obviously high cholesterol saturation index (2.03) was observed as early as five months after colectomy (patient 5). Most patients in the post colectomy group showed increased cholesterol saturation index within 5 to 57 months after colectomy. One patient with familial adenomatosis coli and ileoanal anastomosis (patient 6) showed a relatively low cholesterol saturation index. No significant correlation was observed between the cholesterol saturation index and the time after colectomy (r=0.57, p=0.24).

**CHOLESTEROL NUCLEATION TIME (FIG 2)**
In the colectomy group, cholesterol monohydrate crystals appeared within three days in four of five patients. In contrast, cholesterol crystals did not appear during the observation period in four of five control patients. The colectomy patients had a significantly faster nucleation time than the controls (6.4 (3.8) vs 18.8 (2.2) days, p<0.05).

**ANALYSIS OF GALL STONES OF THE COLECTOMY GROUP**
Gall stones were cholesterol stones by gross inspection. Chemical analysis showed that gall stones from patients 1 and 2 contained...
100% and 80% cholesterol by dry weight, respectively.

Discussion
The current study showed that the biliary lipid composition, cholesterol saturation index, and nucleation time in patients after colectomy resembled values in patients with cholesterol gall stones. These changes are in good agreement with the fact that the gall stones formed in the colectomy group were confirmed by chemical analysis to be cholesterol gall stones.

The present results are consistent with those of Harvey et al who reported an increased cholesterol saturation index and rapid nucleation time after colectomy in patients with ulcerative colitis. Nearly half of their control subjects had a nucleation time of less than six days, whereas cholesterol crystals did not appear within 21 days in most of our control patients. The difference may be due to the fact that patients with ulcerative colitis served as the controls in the study of Harvey et al. Increased excretion of bile acids in ulcerative colitis patients has been reported, even in remission, so the bile acid metabolism might have been changed in their controls.

In the present study, the molar percentage of bile acid decreased while cholesterol and phospholipids increased. The increased cholesterol saturation index after colectomy was a result of changes in the biliary lipids (Table II). Bile acid metabolism after colectomy has been reported by several authors. An increased faecal bile acid excretion has been reported after colectomy with continent ileostomy, conventional ileostomy, or ileal pouch-anal anastomosis. Salemans et al recently investiga ted bile acid levels in colectomy patients with ileal pouch-anal anastomosis and suggested that bile acid malabsorption occurs after colectomy. Thus, the colectomy patients in the present study may have had malabsorption of bile acids.

Biliary bile acid secretion is regulated by its pool size and the turnover rate of the enterohepatic circulation. Rutgeert et al showed that the supersaturated bile is formed as a result of the more reduced biliary output of bile acids than of cholesterol in patients who underwent partial ileocolic resection. They suggested that the partial interruption of the enterohepatic circulation of bile acids reduces the size of the bile acid pool and decreases bile acid secretion. In animal experiments, relatively decreased bile acid secretion has also been reported when enterohepatic circulation has been interrupted. Although a very limited length of terminal ileum was resected in our patients with colectomy, partial interruption of the enterohepatic circulation of bile acids might be present.

Cholesterol absorption is carried out in the upper third of the small intestine and is disturbed only when bile acid absorption is severely affected. The increased proportion of cholesterol in the present study is probably secondary to the decreased bile acid secretion as described above. Thus, we consider that the bile acid malabsorption resulted in the altered biliary lipid composition and the increased lithogenicity in patients with total or subtotal colectomy.

Gall bladder bile acid composition was also changed in patients with colectomy. The appreciable decrease in deoxycholic acid may be the direct effect of colectomy because secondary bile acids are formed and absorbed in the colon. This change is in good agreement with previous studies showing a reduced excretion of secondary bile acids in the ileal effluent in patients with ileostomy. The significantly increased cholic acid concentration in gall bladder bile also suggests that less cholic acid is metabolised further to deoxycholic acid in the colectomy group. It is thus probable that the increased proportion of biliary cholic acid and the decreased proportion of deoxycholic acid may result from reductions in both the 7a-dehydroxylation of cholic acid and the passive absorption of deoxycholic acid in the patients with colectomy. A shorter intestinal transit time and changes in the intestinal microflora may be responsible for the reductions.

The other important finding in this study is the chemical analysis of gall stones obtained from patients with colectomy, since there is no published report of this. The gall stones formed were cholesterol stones. Lithogenic bile appeared soon after colectomy and no correlation was found between the cholesterol saturation index and the time after colectomy (Fig 1). The results suggest that the increased risk of cholesterol gall stone formation occurs shortly after colectomy and persists.

The number of patients with colectomy is small, and the patients who underwent ileal bypass with the ileoanal pullthrough procedure were considered to be a heterogeneous group with regard to the original disease and the reconstruction procedure. Most of these patients had a high cholesterol saturation index and a rapid nucleation time of gall bladder bile irrespective of their original disease or the reconstruction procedure. The biliary bile acid composition was also very similar in these patients. These results suggest that colectomy itself changes the bile acid metabolism, leading to the increased lithogenicity of gall bladder bile.

Subtotal or total colectomy had no effect on the pH, ionised calcium, and total and unconjugated bilirubin of gall bladder bile, which are responsible for pigment gall stone formation. Gall stones formed in the colectomy patients were shown by chemical analysis to consist mainly of cholesterol. The results again support the suggestion that gall bladder bile after colectomy is in a condition to form cholesterol gall stones.

In conclusion, cholesterol gall stones and lithogenic gall bladder bile characterised by an increased cholesterol saturation index and rapid nucleation time were formed in patients after subtotal or total colectomy. Prophylactic cholecystectomy or the administration of cholelitholytic agents may prevent cholesterol
gall stone disease after subtotal or total colectomy.
