‘Sticky’ neutrophils, pathergic arthritis, and response to heparin in pyoderma gangrenosum complicating ulcerative colitis

A D Dwarakanath, L G Yu, C Brookes, D Pryce, J M Rhodes

Abstract
Pyoderma gangrenosum is strongly associated with inflammatory bowel disease and exhibits pathergy, occurring at sites of previous minor trauma. A patient is presented with a 21 year history of extensive ulcerative colitis, who developed pyoderma gangrenosum and arthralgia while receiving high dose corticosteroids for active ulcerative colitis. The arthralgia exhibited pathergy affecting particularly the left temporomandibular joint, which was stressed by an asymmetric bite, and the left elbow, which had been fractured many years previously. This prompted the hypothesis that neutrophils in this condition may be marginated, as a result of increased stickiness of either the neutrophil or the vascular endothelium. The introduction of heparin therapy was associated with rapid resolution of the arthralgia, pyoderma gangrenosum, and ulcerative colitis. (Gut 1995; 37: 585–588)

Keywords: pyoderma gangrenosum, ulcerative colitis, pathergic arthritis, heparin, neutrophils.

Pyoderma gangrenosum is strongly associated with inflammatory bowel disease, particularly ulcerative colitis, which coexists in 34 to 81%. It may occur at any site, commonly affecting the legs, and exhibits pathergy – that is, occurring at sites of previous minor trauma such as needle puncture. Its presence is not closely related to the activity of colitis and it may even occur after colectomy.

In up to 55% of cases pyoderma gangrenosum is associated with an arthritis that may behave more aggressively than the acute seronegative arthropathy that commonly complicates active inflammatory bowel disease. The arthritis may affect smaller joints and can be erosive, sometimes resembling rheumatoid arthritis.

Conventional therapy is empirical, usually with high dose corticosteroids (for example, prednisolone 60 mg/day), but various other agents have been tried with occasional success including topical antibiotics, corticosteroids, azathioprine, cyclosporine, disodium cromoglicate, and dapsone. In cases associated with colitis it may benefit, albeit unpredictably, from bowel resection.

The pathogenesis of pyoderma gangrenosum is unclear. It shares several features with Behcet’s disease including associated inflammatory bowel disease, arthritis, and pathergy.

In both conditions neutrophil abnormalities have been reported, including decreased migration into skin windows, reduced chemotaxis, abnormal phagocytosis, and decreased bactericidal activity.

In the case presented here the pathergic nature of the patient’s arthritis led us to the hypothesis that increased neutrophil adherence to vascular endothelium might be the underlying abnormality. The marginated neutrophils would then be ready to migrate into adjacent tissue in response to minor local trauma. In view of the report of a reduction in the sulphated proteoglycan content of the vascular endothelium in inflammatory bowel disease we speculated that heparin therapy might reverse this defect and reduce neutrophil-endothelium adherence.

Case report
A 42 year old woman with a 21 year history of extensive ulcerative colitis, developed a typical violaceous ulcerating lesion of pyoderma gangrenosum over the left ankle (Fig 1) at a time when her colitis was moderately active. She is a lifelong non-smoker and has no family history of inflammatory bowel disease. Her colitis had not been in complete remission for 20 months and for the two months prior to the development of the skin lesion she had required oral corticosteroid therapy (prednisolone ≥30 mg/day) with which she was compliant, in addition to her usual maintenance therapy of sulphasalazine 1 g twice daily. Two weeks before the appearance of the skin lesion she had developed a widespread severe arthralgia particularly affecting the left temporomandibular joint, left elbow, both knees, and ankle joints. She has an asymmetric bite and the affected temporomandibular joint was on dental review noted to be susceptible to trauma as a result of this asymmetry; similarly the painful elbow had been fractured many years previously but had been pain free for years. The pain from the left temporomandibular joint was so severe she could not take solid food.

On admission haemoglobin was 10.1 g/dl, erythrocyte sedimentation rate 46 mm in one hour, serum C reactive protein 35 mg/l, and albumin 38 g/l. Sigmoidoscopy shortly before admission showed liquid stool and red granular mucosa. A biopsy was not taken from the skin lesion because of the risk of poor healing at that site. In view of the pronounced rise in faecal lactoferrin excretion that we have noted in inflammatory bowel disease and the
Figure 1: Lesion of pyoderma gangrenosum above the left ankle before the introduction of heparin therapy.

Figure 2: The patient’s clinical course, before and after the introduction of heparin therapy, illustrating the improvement in joint pain, stool frequency, and falling serum C reactive protein, these changes occurring while the dose of prednisolone was decreased. Joint pain was assessed using a visual analogue scale. CRP = C reactive protein.

role of lactoferrin in promoting neutrophil adhesion, serum lactoferrin was measured using a sandwich enzyme linked immunosorbent assay (ELISA) and found to be 489 ng/ml, compared with 144 ng/ml (95% confidence limits 17 to 270) for control serum samples (n=18, healthy controls age 16 to 55). Neutrophil adhesion to plastic tissue culture plates was measured by incubation of 10^6 neutrophils in 1 ml RPMI1640 (Gibco, Paisley, UK) for 30 minutes at 37°C on 24 well culture plates (Nunc, Kamstrup, Denmark) followed by washing three times with phosphate buffered saline pH 7.4, staining with Wright’s stain (Sigma Chemical, Poole, UK), and counting of adherent neutrophils in eight high power fields after blind labelling. Neutrophil adhesion was consistently increased (median 59 per high power field (range 30–84, 18 findings)), compared with median 27 (range 2–45) for neutrophils from healthy controls (n=4).

Intravenous heparin (30 000 units/24 hours) was started, with the activated partial thromboplastin ratio between 1.5 and 2.0, and the corticosteroid therapy maintained unchanged at prednisolone 30 mg once daily. There was a rapid improvement in the arthropathy such that she was able to chew a normal diet within two days and there was a decrease in bowel frequency from four liquid stools to two formed stools daily in association with sigmoidoscopic improvement at that time (Fig 2). After 10 days of intravenous heparin therapy, maintenance therapy with subcutaneous calcium heparin was introduced, maintaining an activated partial thromboplastin ratio between 1.5 and 2.0. It was possible to withdraw the prednisolone completely and there was gradual resolution of the pyoderma gangrenosum (Fig 3). The serum C reactive protein and serum albumin both improved during heparin therapy (Fig 2). Sixteen months later the patient remains well without corticosteroid therapy with colitis in complete remission, skin lesion healed, and no joint pain.

Discussion

The dramatic response to heparin in this patient is in keeping with the hypothesis that increased neutrophil-endothelial adherence resulted in generalised margination of neutrophils, which in turn was responsible for the pyoderma gangrenosum and pathergic arthritis. Neutrophil adherence to endothelium was recognised by Dutrochet in 1824 to be an essential initial step of the acute inflammatory response. In pyoderma gangrenosum we speculate that this increased adhesion becomes a more generalised abnormality, either of the neutrophils themselves or of vascular endothelium, and results in neutrophil margination at sites distant from the inflamed bowel. This margination would readily explain the pathergy that typifies the skin lesions (and in this case also the joint involvement).

It is probable that one of the properties of the endothelial sulphated proteoglycans is local inhibition of thrombin formation and that the reduction in endothelial sulphated proteoglycan shown in inflammatory bowel disease would impair this effect and in turn lead to increased leucocyte adhesion. The increased mucosal content and serum lactoferrin content would add to this effect – as lactoferrin is highly charged and a potent stimulator of neutrophil adhesion. Increased neutrophil adherence to nylon, a charge dependent phenomenon, has been reported in inflammatory bowel disease.

Heparin, which is itself a sulphated proteoglycan, has a wide range of effects that can be considered anti-inflammatory; these include:
Heparin therapy for pyoderma gangrenosum.  

(a) inhibition of local formation of thrombin, which itself activates neutrophils and increases the permeability of endothelial cell layers, and inhibition of neutrophil elastase, which is essential for penetration of the endothelium by the neutrophil, (c) binding of chemokines, involved in margination and adhesion, inhibition of leucocyte heparanase, and binding of lactoferrin. Many or all of these properties are also held by the normal endothelial proteoglycans (particularly heparan sulphate). If the endothelial effects are critical as seems likely, the long half life of endothelial bound heparin may mean that intermittent treatment with minimal systemic anticoagulation could be used to achieve this effect on neutrophil-endothelial adhesion.

Increased neutrophil adherence to endothelium resulting in neutrophil margination provides a plausible explanation for pathergy in pyoderma gangrenosum. The impressive effects of heparin therapy in this case, and in cases of refractory ulcerative colitis suggests a need for further therapeutic trials in both conditions.
