Kinetic studies on colonocyte metabolism of short chain fatty acids and glucose in ulcerative colitis

M Rye Clausen, P B Mortensen

Abstract
Short chain fatty acids (SCFAs) are potentially valuable as a topical therapy for distal ulcerative colitis. The mechanism of action is unknown but may involve improved intracellular energy production as previous evidence indicates that colonocyte oxidation of butyrate is impaired in ulcerative colitis. No information is, however, available on human mucosal metabolism of acetate and propionate in either health or disease or the Vmax and Km values of butyrate oxidation. The aim of the study was to assess the kinetic parameters, Vmax and Km, of the complete oxidation of short chain fatty acids and glucose by human colonocytes and to explore whether a metabolic abnormality could be confirmed in patients with ulcerative colitis. Colonocytes were isolated from surgical specimens obtained from 14 patients with ulcerative colitis and eight control subjects. Incubations were performed in the presence of a concentration range of 14C-labelled acetate, propionate, butyrate, and glucose. Oxidation rates were obtained by quantifying the production of 14CO2. Vmax and Km were calculated by computer fitting of the data to a Michaelis-Menten plot. No significant differences were shown in either Vmax or Km values of any of the SCFAs or glucose comparing controls and patients with ulcerative colitis. Comparing the results obtained regarding the individual SCFAs, the most striking difference was the considerably lower Km value of butyrate. The apparent Vmax of acetate tended to be higher than Vmax of propionate and butyrate. Vmax of glucose oxidation was significantly lower compared with the Vmax values of SCFA oxidation. The study shows the ability of isolated human colonocytes to utilise each of the three major SCFAs, but does not support a pathogenic role for defective metabolism of butyrate in ulcerative colitis. The considerably lower Km of butyrate oxidation supports a specific role of butyrate as an energy source for the colonic mucosa in both health and ulcerative colitis.

Keywords: colon, fatty acid oxidation, in vitro, kinetic parameters, short chain fatty acids, ulcerative colitis.

Over the past decade it has become evident that short chain fatty acids (SCFAs) play a greater part in the welfare of colonic mucosa than previously suspected. The principal SCFAs, acetate, propionate, and butyrate, are formed by bacterial fermentation of unabsorbed carbohydrates and tend to be present in the colonic contents (approximately 100 mmol/l) and proportions (60:20:20). SCFAs are readily absorbed from the colonic lumen and once inside the colonocytes, the cellular oxidation of SCFAs is considered to be the major energy source for the epithelial cells.

Clinical trials show that SCFA enemas may ameliorate inflammation in distal ulcerative colitis (UC). The potential mechanism by which SCFAs affect the colonic mucosa is unknown, but evidence that butyrate oxidation is impaired in colonocytes isolated from patients with UC has led to the hypothesis that failure of fatty acid oxidation in UC is an expression of an energy deficiency disease of the colonic mucosa. It has therefore been suggested that local application of higher than normal concentrations of SCFAs may overcome the partial metabolic block in UC by mass action and thereby improve mucosal energy supply. No information, however, is available on the metabolism of acetate and propionate in either health or disease. If the defect of cellular SCFA oxidation is restricted to butyrate the mucosal energy requirements may be met by oxidation of acetate or propionate and irrigation of these two acids may then prove to be the most successful treatment. Because of both the therapeutic implications as well as potential mechanisms involved regarding disease pathogenesis we found it of interest to investigate the complete oxidation of the three major SCFAs and glucose into CO2 by colonic epithelial cells isolated from patients with UC and control subjects. As previous experiments using isolated rat colonocytes have shown that oxidation rates of SCFAs and glucose varies with substrate concentrations in accordance with Michaelis-Menten kinetics, cell suspensions were incubated in the presence of substrates added in concentrations ranging from 0-125 mmol/l to 2 mmol/l (SCFAs) or 4 mmol/l (glucose). The resultant curves obeyed the Michaelis-Menten equation permitting the determination of the kinetic parameters, Vmax and Km.

Methods

Materials
Bovine serum albumin (Fraction V), dithiothreitol (DTT), EDTA, and unlabelled D-glucose were obtained from Sigma Chemical (St Louis, MO, USA). Unlabelled
Mucosal metabolism of SCFAs in ulcerative colitis

acetate, propionate, and butyrate were obtained from BDH Limited (Dorset, UK). Radioactively labelled compounds were obtained from the following sources: [1-14C]-acetate and [1-14C]-propionate from Sigma Chemical (St Louis, MO, USA), [1-14C]-butyrate from Du Pont-NEN Research Products (Boston, MA, USA), and [D-6-14C]-glucose from Amersham (Amersham, UK).

Isolation and incubation of colonocytes

Colonocytes were isolated from fresh surgical specimens obtained at operations performed for moderate or severe ulcerative colitis (n=14; 4 men, 10 women; age 20–75 years, mean 36), carcinoma of the colon (n=8; 1 man, 7 women; age 46–83 years, mean 70), and para-plegia with severe constipation (1 man; 73 years). Originally nine patients were included in the group of colonic cancer. By histological evaluation, however, one patient (female, 72 years) turned out to have Crohn’s disease and was therefore not included in the data analysis. In patients with UC, mucosa was stripped from areas with no visible ulcerations, and at least 5 cm from the carcinoma in patients with colonic cancer. The colonic specimens were washed clear of debris with water, cut open, and pinned out to assist removal of mucosal strips from the muscularis propria with scissors. The strips were cut into 2–3 cm segments and placed in calcium free Krebs-Henseleit saline with 5 mmol/l DTT previously gassed with O2 and CO2 (19:1, vol/vol) for transport to the laboratory.

Isolated cells were prepared as described by Roediger and Truelove, with the exception that hyaluronidase was omitted. Cell suspensions, 1 ml representing 5–15 mg dry wt of epithelial cells, were incubated for 40 minutes in conical flasks equipped with a glass centre well. Incubations were performed in 1 ml of Krebs-Henseleit saline containing 2-5% (wt/vol) bovine serum albumin, 5 mmol/l DTT, and the appropriate substrates. Labelled substrates were evaluated at concentrations ranging from 0.125 to 2 mM for acetate, propionate, and butyrate, and from 0.125 to 4 mM for glucose. In each experiment, identical incubations were run in parallel from which exogenous substrate was omitted. Flasks without cells were included to correct for volatility of SCFAs. Flasks were gassed with O2:CO2 (19:1, vol/vol) for 15 seconds, stopped immediately, and shaken at 90 oscillations/min in a 37°C water-bath. Incubations were terminated by injecting 0.5 ml of 10% perchloric acid through the stopper into the suspension. In a similar manner, the centre wells were filled with 0.5 ml of 10 M NaOH to adsorb CO2. The flasks were shaken for a further two hours on ice to allow the labelled 14CO2 to diffuse and be trapped, after which 0.1 ml of the absorbent were transferred in duplicate to counting vials and mixed with 10 ml of scintillation liquid (Ultra Gold, Packard Instrument, Chemical Operations, Groningen, the Netherlands).

Figure 1: Rate of 14CO2 production from 14C-labelled acetate, propionate, butyrate, and glucose by colonocytes isolated from control subjects and patients with ulcerative colitis. Values are means (SEM).

Analytical methods

Radioactivity was counted in a model 4530 Packard TriCarb liquid scintillation spectrometer (Packard Instrument, IL, USA) and counts were corrected for the non-specific activity generated by perchloric acid. Duplicate measurements of dry weights were obtained by drying 1 ml of cell suspension overnight at 65°C and subtracting the weight of 1 ml of the albumin containing medium.

Calculations

Oxidation rates are expressed as nmol per min per gram dry weight of epithelial cells. Generation of CO2 from 14C-labelled SCFAs or glucose is calculated from the specific activities and trapped 14CO2 in sodium hydroxide. The apparent values of Vmax and Km are calculated by computer fitting of the data to a Michaelis-Menten plot (Eienfitzer, RJ Leatherbarrow, Elsevier, Amsterdam).

Statistics

Data are expressed as means (SEM). Comparisons between different groups were performed by the analysis of variance (ANOVA), equivalent to a t test if only two groups were compared. When a statistically

A significant result was obtained by the ANOVA (p<0.05), group differences were tested by least significant difference.

**Results**

A time course study (20, 40, and 60 minutes) showed that colonocyte oxidation of SCFAs (2 mmol/l) and glucose (4 mmol/l) was linear over 60 minutes in both patients with UC and control subjects indicating efficient metabolic performance of isolated cells during the incubation period (40 minutes). Figure 1 exhibits the rate values of 14CO2 production from 14C-labelled acetate, propionate, butyrate, and glucose as a function of substrate concentrations in controls and patients with UC. The resultant curves obeyed Michaelis-Menten kinetics for all substrates permitting the determination of the kinetic parameters, Vmax and Km (Table).

The apparent Vmax and Km values of SCFAs and glucose oxidation did not differ significantly comparing control subjects and patients with UC (Table). Patients with non-inflamatory colonic diseases belonged to a significantly older age group than patients with UC (Table). Although the Vmax of acetate was significantly higher than Vmax of butyrate, the Km value of glucose was significantly lower than Vmax of butyrate. The Km values of propionate and glucose were not significantly different from those of the Km value of acetate.

As in controls, the Km value of glucose (713 (50) μmol/l) was not significantly different from the Km value of acetate (Table).

Figure 2 shows the production rates of ATP as a function of substrate concentrations. The values of ATP production are calculated on the basis that complete oxidation of 1 mol acetate, propionate, butyrate, and glucose provides 10, 18, 27, and 36 mol of ATP, respectively. At each concentration the production rates of ATP were similar comparing acetate, propionate, and glucose but significantly higher for butyrate in both UC and controls.

**Discussion**

The concept of SCFAs being a critical luminal nutrient source for the colonic mucosal cells and of there being a potential ‘metabolic block’ in UC was originally proposed by Roediger in 1980. In cell suspensions of isolated human colonocytes (resection specimens obtained from patients with carcinoma of the colon), butyrate accounted for more than 70% of the oxygen consumption, and the hypothesis was put forward that fatty acids of anaerobic bacteria are an important source of energy for the colonic mucosa. In patients with quiescent and acute UC the oxidation rates of butyrate to CO2 and ketones were significantly lower than in control tissues, and the decrease correlated with the state of the disease. Enhanced glucose and glutamine utilisation compensated for the decreased oxidation of butyrate, as measured by lactate and ammonia production, respectively. It was therefore suggested that failure of fatty acid (butyrate) oxidation in UC is an expression of an energy deficiency disease of the colonic mucosa. In 1988 Vernia et al. investigated faecal water samples from patients with UC and Crohn’s disease, in UC concentrations of SCFAs, especially butyrate, were decreased compared with those from healthy controls or Crohn’s disease. When patients with UC were classified according to the activity of colitis, concentrations of SCFAs were high in quiescent and mild disease, but significantly decreased in the severe form. These findings, and the previous finding of impaired butyrate oxidation in colitic cells, prompted the authors to suggest that restoration of normal luminal concentrations of SCFAs in UC could be considered as a therapeutic manoeuvre.

Clinical results concerning the treatment of distal UC with rectal instillation of SCFAs have indeed been encouraging. Breuer et al. tested a combination of SCFAs in patients with refractory distal UC. In their open trial, nine of 10 patients who completed the study showed clinical, endoscopic, and histological improvement by the end of six weeks. The authors have recently reported the results of the first 41 patients in an ongoing double blind, placebo controlled trial of SCFA rectal irrigation in patients with left sided UC. These interim results seem to confirm the earlier uncontrolled findings using the same protocol. In a randomised, prospective comparison of corticosteroid, mesalazine, and...
SCFA enemas, Senagore et al found SCFAs to be equally effective when directly compared with corticosteroid and mesalamine preparations in the treatment of proctosigmoiditis. Steinhardt et al evaluated the effect of butyrate alone rather than the SCFA mixture in patients with distal UC whose disease was refractory to conventional treatments. In this open label study, six of 10 patients responded to treatment. Four of these six had complete responses. Scheppech et al using a single blind crossover design, showed clinical, endoscopic, and histological improvement after just two weeks of treatment with butyrate enemas, whereas no change was seen under placebo conditions. Thus, local application of a mixture of SCFAs or butyrate alone seems to ameliorate inflammation in patients with UC.

Regarding the mechanism of action, the prevailing hypothesis involves improved intracellular energy production, which is achieved despite an assumed abnormality of mitochondrial SCFA oxidation by restoring luminal concentrations of SCFAs, possibly to values higher than normal and subsequent 'mass action'. The existence of a luminal deficiency of SCFAs has, however, not been universally accepted. Although some authors have shown reduced concentrations of SCFAs in faeces of patients with severe UC, others have found that values are normal, or even increased in this setting. The last study by Roediger et al measured luminal concentrations of SCFAs in patients with UC, which were graded according to mucosal changes into mild, moderate, or severe inflammatory activity. Concentrations of acetate, propionate, and butyrate were all increased in severe UC whereas only butyrate concentrations were significantly raised in patients with mild and moderate inflammatory activity. The authors suggested that the persistently raised concentrations of butyrate in all severities of mucosal inflammation could reflect the previously shown inability of butyrate utilisation in UC. In that case, it would be less plausible that the response of UC to SCFA administration is mediated through increased accessibility of butyrate.

To our knowledge this is the first study to investigate the colonic mucosal metabolism in patients with UC by use of isolated colonoocytes since the study performed by Roediger in 1980. The similar oxidation of butyrate in controls and patients with UC shown by our study is in contrast with the results previously obtained. With reference to luminal concentrations, Roediger considered butyrate concentrations of 10 mmol/l as physiological. By use of separated cells, however, not only the mucosal cell membranes become exposed to the surrounding solution but also the serosal parts, which in vivo are SCFA concentrations of about 1/100 to 1/1000 of the luminal concentrations, and recent studies on isolated rat colonoocytes have shown Km values of SCFA oxidation in the range of 0.2-0.5 mmol/l indicating that intracellular concentrations may be closer to portal rather than luminal concentrations. The incubations in our study were therefore performed in the presence of extracellular concentrations ranging from 0.125 to 2 mmol/l. The resultant curves obeyed Michaelis-Menten kinetics for all substrates permitting the determination of the kinetic parameters, Vmax (maximum rate of metabolism) and Km (the substrate concentration at which the reaction rate has half its maximum value) showing that the maximum rate of SCFA oxidation by isolated colonoocytes is well achieved at concentrations around 2 mmol/l (Table). The Km values of acetate, propionate, and butyrate were very similar to the values obtained by isolated rat colonoocytes, and addition of butyrate in concentrations of 10 mmol/l – that is, about 100 times higher than the Km value, might be unphysiological. Artefactual abnormalities may therefore be introduced, and toxic effects of sodium butyrate at concentrations above 2 mmol/l have been reported in cultured human cancer cell lines. If cells from inflamed epithelium are more prone to toxicity, artefactual differences could hypothetically have been introduced in studies using concentrations of butyrate which, according to the obtained Km values, are unphysiologically high. The presence of increased values of luminal bacterial metabolites (for example,
mercapto fatty acids, sulphides) causing specific inhibition of fatty acid oxidation in colonic epithelial cells has been proposed to be the initiating event of the disease process that leads to an immune response and colitis.\textsuperscript{28,29} If this is correct, a more thorough cell wash may have eliminated some inhibitory factor(s), and the discrepancy between our and Roediger's findings might be based on minor differences, for example, cell washing procedure.

By use of a different technique, two further studies have investigated the metabolic performance of colonic epithelial cells in patients with UC. The study by Finnie \textit{et al}\textsuperscript{30} compared the oxidation of butyrate in mucosal biopsy specimens obtained from patients with longstanding quiescent UC and controls. No differences in butyrate oxidation were established. An explanation for the discrepancy between their and Roediger's findings could be the use of different techniques. The study by Chapman \textit{et al}\textsuperscript{31} however, did in fact show a significantly lower rate of butyrate oxidation in biopsy specimens obtained from patients with quiescent UC. Nevertheless, an important anxiety over the use of biopsy specimens is, in our opinion, that the size of specimens may differ, resulting in different proportions of actively metabolising (mucosal cells) and inactive (cells of lamina propria/submucosa) tissue, which may be a problem as the results are expressed per g protein.\textsuperscript{30,31}

This study showed that isolated human colonocytes can utilise each of the major SCFAs. No major differences in the apparent Vmax values of CO\textsubscript{2} production from acetate, propionate, and butyrate were seen (Table). In the assessment of the relative importance of the individual SCFAs in the energy generating process, however, the order of energy contribution may be of more relevance. Calculated on the basis that complete oxidation of 1 mol acetate, propionate, and butyrate provides 10, 18, and 27 mol ATP, respectively,\textsuperscript{18} a relative order of energy contribution of butyrate>acetate=propionate is found (Fig 2). The importance of butyrate as an energy source for the colonic mucosa is further emphasised by the finding that it had the lowest Km showing that butyrate may serve as a more readily oxidised fuel than propionate and acetate at low concentrations (<200 \textmu mol/l). In vivo, the colonic mucosa is exposed to very high luminal concentrations of SCFAs, but intracellular concentrations are unknown and may be closer to portal blood concentrations, which are in the range of 114–258 \textmu mol/l for acetate, 32–88 \textmu mol/l for propionate, and 9–29 \textmu mol/l for butyrate\textsuperscript{24,25} – that is, remarkably close to the reported Km values of SCFA oxidation.

No differences in Vmax or Km values of glucose oxidation were found comparing patients with UC and control subjects. In colonocytes isolated from patients with UC, Roediger reported an increased rate of glucose utilisation, measured as lactate production. The present lack of a corresponding increase in the rate of CO\textsubscript{2} production is in agreement with the results of Chapman.\textsuperscript{31} The apparent Vmax of glucose oxidation was significantly lower compared with the Vmax values of SCFA oxidation. However, assuming that complete oxidation of 1 mol glucose provides 36 mol of ATP,\textsuperscript{18} the maximum energy contribution from glucose oxidation is in fact comparable with the energy contribution from acetate and propionate (Fig 2) showing that the energy requirements of human colonocytes may be supported by oxidation of blood borne glucose.

This study has shown the ability of isolated human colonic cells to utilise each of the three major SCFAs. The considerably lower Km of butyrate oxidation shows that butyrate is metabolised more avidly than acetate and propionate at low concentrations and supports a specific role of butyrate as an energy source for the colonic mucosa. Although other effects of SCFAs than their role as energetic fuels may provide additional explanations as to how they seem to improve UC, the results suggest that SCFA solutions should include butyrate in the treatment of UC, not because increased luminal concentrations may overcome a metabolic block but because butyrate seems to be an excellent fuel for colonocytes in patients with UC.
