Effect of *c-kit* ligand, stem cell factor, on mediator release by human intestinal mast cells isolated from patients with inflammatory bowel disease and controls

S C Bischoff, S Schwengberg, K Wordelmann, A Weimann, R Raab, M P Manns

Abstract

The regulation of mediator release in human intestinal mast cells is largely unknown. Apart from IgE receptor crosslinking no secretagogues have been described so far. This study examined the effect of two cytokines (*c-kit* ligand and interleukin 3) and other agonists on human intestinal mast cell function. Cells were isolated from surgery specimens of 47 patients undergoing intestinal resection because of tumours or inflammatory bowel disease. Cell suspensions contained 3.6% mast cells (mean of 50 experiments). After preincubation without or with *c-kit* ligand or interleukin 3, cells were stimulated by IgE receptor crosslinking, C5a or formyl-methionyl-leucyl-phenylalanine (fMLP). Histamine and sulphido-leukotriene release was measured in supernatants. The sequential stimulation of the cells with *c-kit* ligand and IgE receptor crosslinking induced the release of high amounts of histamine and leukotrienes, whereas each agonist by itself induced only marginal mediator release. Interleukin 3 induced no release by itself, but enhanced the IgE receptor dependent release, possibly by an indirect mechanism. No significant mediator release was seen in response to C5a and fMLP, even if the cells were pretreated with *c-kit* ligand. The mediator release, particularly that of leukotrienes, was higher in cells isolated from actively inflamed tissue from patients with inflammatory bowel disease compared with controls. In conclusion, it was found that, apart from IgE receptor crosslinking, *c-kit* ligand and interleukin 3 regulate mediator release in human intestinal mast cells. The enhancement of mediator release by cytokines may be of particular relevance in the pathogenesis of inflammatory bowel diseases and food intolerance reactions. (*Gut* 1996; 38: 104–114)

Keywords: mast cells, histamine release, *c-kit* ligand, interleukin 3, inflammatory bowel disease.

Human mast cells are characterised by metachromatic cytoplasmic granules containing proteoglycans, histamine, and proteases, and by the high affinity IgE receptor on their cellular surface.^{1–3} They are typically located in close

association with tissue forming barriers such as the skin, mucosa, and submucosa of the gastrointestinal and the respiratory tract, and blood vessels, but also in muscular organs such as the heart and the uterus. Mast cells exert biological effects by releasing preformed mediators stored in the granules and de novo synthesised mediators such as leukotrienes, prostaglandins, and cytokines.^{3,4} The role of human mast cells in mediating allergic reactions is well known. In addition, there is increasing evidence that mast cells participate in chronic inflammatory processes such as delayed type hypersensitivities, fibrosis, and neuroimmunological disorders.^{1–5} Other studies suggest that mast cells not only exert proinflammatory effects but also participate in regulating repair processes such as wound healing and tissue remodelling.^{3,6} However, the pathophysiological role of mast cells in the human intestinal tract is largely unknown. Some studies indicate that intestinal mast cells may participate in food hypersensitivity reactions and other diseases such as inflammatory bowel disease.^{7–14} The significant occurrence of this cell type in the gut and the broad spectrum of activities of mast cell derived mediators suggests that this cell type could play a particular part in physiology and pathophysiology of the intestinal tract.

The regulation of mast cell activation is poorly understood. Apart from IgE receptor crosslinking by allergen or in vitro by IgE receptor antibodies, no triggers for mediator release have been described for human mucosal mast cells of the lung or the intestine.^{2,3} In contrast, human skin mast cells can be triggered for mediator release by IgE dependent and IgE independent stimuli such as the anaphylatoxin C5a and the neuropeptide substance P.¹⁵ Rat peritoneal mast cells release histamine in response to nerve growth factor, interleukin 3 (IL 3), and substance P.^{1,2} However, human lung and skin mast cells do not release mediators in response to nerve growth factor and substance P, and they lack the IL 3 receptor,^{16,17} showing a fundamental difference between human and rodent mast cells. Several studies showed that particular growth factors also regulate effector functions in mature cells. For example, the haematopoietic growth factors IL 3, IL 5, and GM-CSF promote the development of basophils and eosinophils, and strongly modulate the release of mediators in mature basophils and eosinophils. These three cytokines induce no or only marginal mediator release in themselves, but strongly enhance the

release reaction induced by different IgE dependent and IgE independent triggering agents.¹⁸⁻²⁰ This effect has been termed 'priming' and was seen in basophils, eosinophils, neutrophils, and monocytes in an analogous way, and thus seems to be a general mechanism for the regulation of inflammatory effector cell functions. By contrast, the knowledge on cytokines modulating human mast cell function is poor. In the rodent system, a number of cytokines (IL 3, IL 4, IL 9, IL 10) could be identified that regulate the development or the effector functions, or both of mast cells.² However, these findings could not be transferred to the human system. All these cytokines failed to affect mediator release in human lung mast cells, further emphasising the functional difference between rodent and human mast cells.¹⁶ The effect of cytokines on human intestinal mast cells has not been examined before.

Recently, a novel growth factor named stem cell factor or *c-kit* ligand has been identified in rodents and humans.²¹ *C-kit* ligand binds to the proto-oncogene *c-kit* and acts as a growth factor on bone marrow progenitor cells in synergism with IL 3, G-CSF, GM-CSF, and erythropoietin. In particular, it promotes the development of mast cells from CD34+ stem cells in vitro and in vivo. Apart from its role as a growth factor for mast cells and other bone marrow derived cell lineages, the biological relevance of *c-kit* ligand is poorly understood. In previous studies, we showed that *c-kit* ligand strongly modulates the function of mature human lung mast cells.^{16, 22} A short preincubation with *c-kit* ligand enhances the release of histamine and leukotrienes in lung mast cells in response to IgE receptor crosslinking. In addition, *c-kit* ligand induces mediator release in human skin mast cells and participates in the pathogenesis of cutaneous mastocytosis.^{23, 24} Thus, *c-kit* ligand is a unique cytokine modulating human lung and skin mast cell function. We have examined the effect of two cytokines, *c-kit* ligand and IL 3, on mediator release by human intestinal mast cells. Cells were isolated from tissue specimens obtained from patients undergoing surgery for complications of inflammatory bowel disease. Normal tissue derived from tumour patients undergoing bowel resection served as control. The release reaction in response to *c-kit* ligand and other agonists was compared in mast cells isolated from different intestinal sections.

Methods

Patients

Fifty experiments were performed with mast cells isolated from surgery specimens of human intestinal tissue. The study includes 47 patients; 25 patients with intestinal tumours (six colon carcinoma, nine rectum carcinoma, four sigmoid carcinoma, six pancreas carcinoma with resection of the duodenum), 10 patients with active Crohn's disease, two patients with active ulcerative colitis, and 10 patients with other intestinal diseases (two duodenal polyps, three colon polyps, one intestinal sarcoma, one x ray induced stenosis, two diverticulosis). Permission to conduct the study on intestinal tissue was given by the ethical committee of the Medical School of Hannover. Table I gives further patient data. Inflamed tissue was obtained from 13 patients (10 Crohn's disease, two ulcerative colitis, one inflamed colon polyp). Macroscopically normal tissue was obtained from 37 patients (25 tumour disease, three Crohn's disease, nine other disease). Thus, both inflamed and non-inflamed tissue could be obtained in three of the patients with Crohn's disease. Non-inflamed tissue from patients with no evidence for intestinal inflammatory disease was taken from macroscopically normal areas of the resected tissue most far away from the tumour and served as control tissue (n=34).

Reagents and buffers

HEPES, D-glucose, gelatin type B, chymopagain, and acetylcystein were from Sigma (München, Germany); ampicillin was from Bayer AG (Leverkusen, Germany); gentamycin, phosphate buffered saline (PBS) buffer without MgCl₂/CaCl₂ was from Gibco (Berlin, Germany); metronidazol was from Fresenius AG (Bad Homburg, Germany); DNase, bovine serum albumin fraction V, pronase, collagenase D, elastase were from Boehringer AG (Mannheim, Germany). All other chemicals were of highest purity available. Tyrode's solution contains 137 mM NaCl, 2.7 mM KCl, 0.36 mM Na₂HPO₄, and 5.55 mM glucose. TE is Tyrode's solution containing 2 mM EDTA. TEA is TE containing antibiotics (ampicillin 200 µg/ml, gentamycin 200 µg/ml, metronidazol 40 µg/ml). TGMD is Tyrode's solution supplemented with 1.23 mM MgCl₂, 15 µg/ml DNase, and 1 mg/ml gelatin.

HEPES buffer contains 20 mM HEPES, 125 mM NaCl, 0.5 mM D-glucose, and 5 mM KCl. HA is HEPES buffer supplemented with 0.25 mg/ml bovine serum albumin. HACM is HA supplemented with 1 mM CaCl₂ and 1 mM MgCl₂.

Cell stimuli

The soluble form of purified human recombinant *c-kit* ligand was kindly provided by Hoffmann-La Roche (Basle, Switzerland). Human recombinant IL 3 was a gift of Sandoz (Basle, Switzerland). *C-kit* ligand and IL 3 were diluted in HEPES buffer containing 1 mg/ml bovine serum albumin to a concentration of 100 µg/ml (*c-kit* ligand) and 10 µg/ml (IL 3). The cells were incubated with final concentrations of 100 ng/ml *c-kit* ligand or 10 ng/ml IL 3. Mast cells were triggered by the purified antibody mAb 29C6, which is directed against a non-IgE binding epitope of the high affinity IgE receptor α chain. This antibody, which binds with high affinity to the Fcε receptor (K_d=3.2 nM) was obtained from Hoffmann-La Roche (Nutley, NJ). It was diluted to 50 µg/ml and used at a final concentration of 100 ng/ml. Formyl-methionyl-leucyl-phenylalanine (fMLP) was from Bachem AG, Bubendorf, Switzerland, and was diluted in PBS/20 mM HEPES to a concentration of 250 µM, and used at a final concentration of 2.5 µM. C5a was purified from human serum as described,¹⁵ and used at a final concentration of 10 nM. All substances were stored in small aliquots at -80°C. The final concentrations of the stimuli have been selected with the intention to use maximally effective concentrations. Because of the limited cell numbers that could be isolated from the patients, dose response experiments could not be performed. Therefore, we chose the concentrations from data in published reports. Dose response studies performed in human lung mast cells showed that *c-kit* ligand is maximally effective above 10 ng/ml, mAb 29C6 at 100 ng/ml.¹⁶ IL 3, C5a, and fMLP do not affect human lung mast cells but do affect human basophils. In such experiments, IL 3 has been shown to be maximally effective above 1 ng/ml, C5a above 1 nM, fMLP above 1 µM.^{18,19} Thus, based on the assumption that the results obtained with human lung mast cells and basophils are transferable to

intestinal mast cells the concentrations of agonists used should be maximally effective.

Cell preparation

Human lamina propria and submucosa cells containing mast cells were isolated from intestinal specimens by a four step enzymatic tissue dispersion method as described previously¹⁶ with some modifications. Immediately after resection, the tissue was placed in ice cold TEA solution and stored at 4°C. The tissue was processed either immediately (within one hour after resection, 21 experiments) or the following day (15–20 hours after resection, 29 experiments). Cell isolation was started by separating the mucosa/submucosa from the muscularis/serosa by scissors, and both the whole tissue and the separated mucosa/submucosa was weighed (wet weight; Table I). The separated tissue was cut into 1×1 cm fragments and incubated in TE solution containing 1 mg/ml acetylcystein for 10 minutes at room temperature to remove mucus, and then in TEA solution containing 5 mM EDTA for 15 minutes at 37°C to detach epithelial cells. After washing in TE solution, the tissue was incubated in TE containing 3 mg/ml pronase and 0.75 mg/ml chymopapain at room temperature. During this first digesting step the tissue was chopped finely with scissors. After 30 minutes the free cells (fraction 1) were separated from tissue fragments by filtration through a polyamid Nybolt filter (pore size 300 µm, Swiss Silk Bolting Cloth Manufacturing, Zürich, Switzerland). The remaining tissue fragments were washed in TE and the first digestion step was repeated at 37°C (fraction 2). The tissue fragments were then washed in TGMD solution and incubated twice for 30 minutes at 37°C in TGMD containing 1.5 mg/ml collagenase D and 0.15 mg/ml elastase. Again, the freed cells were separated from the digested tissue by filtration (fraction 3 and 4). The cells of fraction 1 and 2 and the cells of fraction 3 and 4 were pooled, washed in HA buffer, filtered through a Nybolt filter (pore size 100 µm), washed again, and resuspended in HA buffer.

Cell counting and differentiation

In all experiments, cell fraction 1+2 and cell

*MC=mast cells, EO=eosinophils, NEU=neutrophils, LY=lymphocytes, Other=other cell types (tissue cells); data are presented as mean (SEM). Bold values show criteria, the variables of which influence the number/percentage of cells (analysis of variances, see Methods).

fraction 3+4 were counted in a Neubauer counting chamber (diluted 1:10 in Türk's solution) and differentiated (cytacentrifuge smears stained with May-Grünwald/Giemsa). Fraction 1+2 contained 35 (6) million cells (mean (SEM) of 50 experiments) and 0.51 (0.13) million MC (=1.6%), fraction 3+4 contained 71 (7) million cells and 2.09 (0.32) million mast cells (=3.6%). The mean total cell harvest was 8.5 million cells per g tissue (=20.2 million cells per g mucosa/submucosa), the mast cell harvest was 0.21 million mast cell per g tissue (=0.51 million mast cells per g mucosa/submucosa). Table II shows the composition of the isolated cell suspensions used for the release experiments (fraction 3+4). Trypan blue staining showed 70% (fraction 1+2) and 85% (fraction 3+4) intact cells, the damaged cells being nearly exclusively epithelial cells. No difference was seen in viability of mast cells after overnight storage of the tissue before starting the cell isolation. By contrast, when comparing the cells isolated immediately after surgery and one day later, the second preparations showed higher percentages of mast cells (Table II) and higher numbers of granules in the cytoplasm suggesting a 'reconstitution' of mast cell granules during the storage of the tissue.

Mediator release assay

Only cells of fraction 3+4 were used for release experiments, because fraction 1+2 contained comparatively high numbers of neutrophils (mean: 7.6%, versus 1.5% in fraction 3+4), which may result from a contamination with blood cells. To minimise the risk of contaminating blood derived basophils (0.21% in fraction 1+2, <0.1% in fraction 3+4) and to enhance the percentage of mast cells, the cell fractions 1+2 were discarded. Prior to the experiment, cells of fraction 3+4 were suspended in HACM buffer at a concentration of $3.6 (0.4) \times 10^6$ cells per ml (corresponding to $100 (11) \times 10^3$ mast cells/ml, mean (SEM), range: $10\text{--}310 \times 10^3$ mast cells/ml) and distributed into tubes (1 ml/tube). Experiments were only performed if fraction 3+4 contained at least 100×10^3 mast cells in total. The release experiments were performed in a shaking water bath at 37°C as described.¹⁸⁻²⁰ After a warming up period of 10 minutes the cells were preincubated with or without cytokines for 15 minutes, followed by the addition of the triggering agent. The release reaction was stopped 35 minutes after addition of the triggering agent by placing the tubes in ice cold water (total incubation time=one hour). Cells were separated from supernatants by centrifugation ($400 \times g$, 10 min, 4°C) and the supernatants were stored at -80°C until histamine and sulphidoleukotrienes were measured.

Measurements of mediators

For each experiment the total amount of histamine per tube was determined. For each experiment the total amount of cellular histamine was measured in quadruplicates. Cell

suspensions were diluted 1:1 in distilled water and sonicated. The lysates were centrifuged ($1000 \times g$, 10 min, 4°C) and supernatants were also stored at -80°C for histamine measurements. Histamine was measured by a competitive solid phase radioimmunoassay using an antibody recognising acetylated histamine (Dianova-Immunotech SA, Hamburg, Germany). Histamine content per mast cell was 0.60 (0.16) pg/mast cell (mean (SEM), $n=35$, see Table II). Histamine release was expressed as per cent release of total cellular histamine content. Sulphidoleukotrienes were measured by a fluid phase radioimmunoassay using a mAb recognising leukotriene C4 (LTC4) equally well as its metabolites LTD4 and LTE4.²⁰ Such an antibody is preferable to other mAbs specific for LTC4, as the use of a mAb with equal affinity for all sulphidoleukotrienes eliminates the possibility that the leukotriene measurements are dependent on variations in LTC4 metabolism. Leukotriene data were expressed as pg per 10^6 mast cell. Eleven of 50 experiments (22%) had to be excluded from analysis of histamine release, because total cellular histamine content per tube was below 5 nM, and therefore, mediator release was no longer measurable (detection limit of the assay=1 nM). Twenty nine of 50 experiments (58%) had to be excluded for analysis of sulphidoleukotriene production, because no leukotrienes could be detected under any experimental condition (detection limit of the sulphidoleukotriene assay=3 pg/tube). In nine experiments both histamine and leukotrienes were not detectable. The number of mast cells per tube was slightly smaller in the excluded experiments compared with the experiments in which mediators were measurable. Nevertheless, these small differences in mast cell numbers are not sufficient to explain the failure to detect mediators in, respectively, 11 and 29 of 50 experiments. It is probable that some cell preparations may be damaged during tissue resection or during the five hours cell isolation procedure, although such functional deficiencies are not necessarily shown by Trypan blue staining.

Immunohistochemistry

Mucosal biopsy specimens from 52 patients (20 with Crohn's disease, 22 with ulcerative colitis, 10 controls without evidence of inflammatory bowel disease) were fixed in paraformaldehyde 4%, embedded in paraffin wax, and sequentially sectioned at 3 µm. Sections were applied to slides coated with APES (3-aminopropyl-triethoxysilan), and, after deparaffinisation and hydration, pretreated with target unmasking fluid (Dianova, Hamburg, Germany), hydrogen peroxide 3%, and goat non-immune serum (Dako Diagnostics, Hamburg, Germany). Subsequently, sequential sections were incubated for 60 minutes at room temperature with the primary antibody, either mouse antihuman tryptase mAb (Chemikon, Temecula, CA) at 0.25 µg/ml, or affinity purified rabbit antihuman *c-kit* pAb (Oncogene Science, Uniondale, NY) at 2.5 µg/ml. After washing, sections were

incubated with a biotinylated secondary antibody for 30 minutes, streptavidin conjugated horseradish peroxidase for 30 minutes, and hydrogen peroxide for five minutes (all reagents from Dako Diagnostics). Positive cells within a defined area of lamina propria ($400\ \mu\text{m} \times 500\ \mu\text{m}$) were counted and expressed as cells per mm^2 of lamina propria.

Statistics

All experiments were performed in duplicate and each supernatant was measured twice. Thus, four values were obtained for each condition, and the mean was calculated. Data from several experiments are presented as mean (SEM), if not indicated otherwise. For comparison of multiple experimental conditions or more than two patient groups data were analysed by analysis of variance (multiple comparisons) using the software package SPSS release 6.0. For multiple comparisons of paired group means the Duncan method was used provided that differences of the means could

be assumed.²⁵ If two patient groups were compared, the two tailed *t* test for independent samples was used. For correlation analyses, the correlation coefficient and the probability for the hypothesis that the slope of the regression curve is different from zero (modified *F* test) was calculated.

Results

Effect of *c-kit* ligand on mediator release by human intestinal mast cells

Figure 1 shows that human intestinal cells containing mast cells spontaneously release histamine and sulphidoleukotrienes within an incubation time of one hour at 37°C . Both *c-kit* ligand and mAb 29C6 by themselves induced the release of small amounts of histamine and sulphidoleukotrienes albeit not significant in statistical means. Most interestingly, the preincubation with *c-kit* ligand rendered cells capable of releasing large amounts of preformed and de novo synthesised mediators in response to otherwise hardly effective IgE receptor crosslinking. As expected, the receptor independent stimulation by ionomycin, which served as a positive control in those experiments, caused the most pronounced release reaction in intestinal mast cells. The sequential stimulation of mast cells with *c-kit* ligand and mAb 29C6 induced a release reaction comparable to that induced by 'unphysiological' receptor independent triggers such as ionomycin. In almost all experiments preincubation with *c-kit* ligand caused an enhancement of the IgE receptor dependent release of histamine (mean (SEM) 46 (10)% enhancement, range: 3–250%, $p < 0.01$) and of leukotrienes (235 (112)% enhancement, range: 4–2113%, $p < 0.05$), albeit to variable degrees.

Figure 1: Effect of *c-kit* ligand (KL) on mediator release by human intestinal mast cells. Cells were preincubated in buffer (O, 29C6, Iono) or with 100 ng/ml human KL (KL, KL+29C6) for 15 minutes and then stimulated with 100 ng/ml anti-IgE receptor mAb 29C6 (29C6, KL+29C6) or with 1 μM ionomycin (Iono) for 35 minutes at 37°C . O=buffer control. Histamine release (expressed as % of total cellular histamine before stimulation, upper panel) and leukotriene production (pg sulphidoleukotrienes per 10^6 mast cells, lower panel) is shown. The mean (SEM) of 33 (upper panel) and 18 (lower panel) experiments performed in duplicate is shown. The horizontal line in the 4th column from the left (KL+29C6) shows the predicted additive effect of KL and mAb 29C6. Statistical analysis (Duncan method, see text): * $p < 0.05$, ** $p < 0.01$ for a significant difference to the spontaneous release (O), other significant differences in histamine release: Iono versus KL, Iono versus 29C6, Iono versus KL+29C6, KL+29C6 versus KL, KL+29C6 versus 29C6 (all $p < 0.01$), in leukotriene production: Iono versus 29C6, KL+29C6 versus 29C6 (both $p < 0.05$).

IL 3 enhances mast cell mediator release

In contrast with *c-kit* ligand, the haematopoietic growth factor IL 3 induced almost no mediator release by itself in human intestinal mast cells. However, IL 3 also enhanced the histamine and leukotriene release induced by stimulation with the mAb 29C6. The enhancement by IL 3 preincubation was clearly less pronounced compared with the effect of *c-kit* ligand preincubation (Fig 2).

Mediator release by fMLP and C5a

The anaphylatoxin C5a and the bacterial product fMLP induced small amounts of histamine release (statistically not significant, Fig 3) and sulphidoleukotriene production (data not shown). In contrast with IgE receptor crosslinking, the effects of both chemotactic agonists were not enhanced by *c-kit* ligand preincubation suggesting that their marginal effects on mediator release may be mast cell independent.

Mast cells as the source of histamine and leukotrienes

Figure 4 (A) shows that the total histamine per

Figure 2: Effect of interleukin 3 (IL 3, 10 ng/ml) on mediator release by human intestinal mast cells. The experimental procedure and the concentrations of the other agonists are described in Fig 2. The mean (SEM) of 14 (upper panel, histamine release) and five (lower panel, leukotriene production) experiments performed in duplicate is shown. Statistical analysis (Duncan method, see text): * $p < 0.05$; ** $p < 0.01$ for a significant difference to the spontaneous release (O), other significant differences in histamine release: IL3 versus IL 3 ($p < 0.01$), IL3 versus 29C6 ($p < 0.05$), KL+29C6 versus IL 3 ($p < 0.05$).

tube measured after cell lysis correlated with the mast cell numbers in the tubes. Furthermore, the absolute amounts of histamine and leukotrienes released after stimulation with *c-kit* ligand and mAb 29C6 correlated with the mast cell numbers (data not shown). This may show that mast cells are indeed the source of histamine and leukotrienes released after IgE receptor crosslinking. The potentiation of IgE dependent mediator release by *c-kit* ligand was not affected by the presence of contaminating tissue cells, as identical results were obtained by unfractionated dispersed intestinal cells and mast cell preparations depleted of tissue cells by Percoll gradients (purity 20–50%, data not shown). The source of mediators cannot be attributed definitively to mast cells, however, unless human intestinal mast cells cannot be purified to higher degrees. Interestingly, the release of leukotrienes induced by sequential stimulation with *c-kit* ligand and mAb 29C6 was negatively correlated with the percentage of mast cells in the cell suspensions (Fig 4 (B)). This may show that degranulated mast cells may contribute to the leukotriene synthesis. In particular, the cell preparations, in which only small numbers of mast cells were counted, may contain 'invisible mast cells', which have

already lost their granules by prior in vivo stimulation or by cell damage during cell preparation.

Correlation of mediator release in response to different stimulation protocols

The experiments show a strong correlation between the mediator release in response to mAb 29C6 alone and mAb 29C6 after *c-kit* ligand preincubation ($r=0.72$ and 0.93 for histamine and leukotriene release, respectively; Fig 4 (C) and (D)). The correlation was slightly weaker between the release by *c-kit* ligand+mAb 29C6 and receptor independent ionomycin (Fig 4 (E) and (F)), suggesting that the 'releasability' is not primarily depending on the agonist used for mast cell triggering. A weak positive correlation could be also found between histamine and leukotriene release in response to *c-kit* ligand+mAb 29C6 ($r=0.50$, $p < 0.05$, $n=16$, data not shown).

Mast cell counting and mediator release in patients with inflammatory bowel disease

The percentage of mast cells in cell suspensions derived from patients with tumours (normal tissue) and Crohn's disease did not differ significantly (Table II). Also the grade of inflammation and the site of tissue resection did not influence the number of isolated mast cells. Higher mast cell percentages were found, however, if the tissue was processed a day after tissue resection compared with cell preparations isolated within two hours. As it is unlikely that mast cells proliferate under these conditions within 24 hours, a kind of 'reconstitution' of mast cell granules may occur in tissue within 24 hours after resection. This would explain why more mast cells become visible in light microscope examination after one day. The number of eosinophils varied in the cell preparations depending on the kind of disease, the presence of active inflammation, and the site of tissue resection. High eosinophil percentages were found in actively inflamed tissues and in tissue derived from patients with Crohn's disease or ulcerative colitis. Also neutrophils and lymphocytes predominated in preparation derived from actively inflamed tissue or from patients with inflammatory bowel disease. The highest histamine content per mast cell was found in mast cells isolated from patients with Crohn's disease or ulcerative colitis, and in mast cells derived from the small intestine (Table II). Our data suggest that the release reactions are dependent on the diagnosis, the presence of active inflammation, and the site of tissue resection, but not on age, sex or time of tissue processing (analysis of variances, overall $p < 0.05$). For example, Fig 5 shows that mast cells isolated from actively inflamed tissue (nine Crohn's disease, one ulcerative colitis) release higher amounts of mediators than mast cells from macroscopically normal tissue. Significant differences were seen for histamine release in response to sequential stimulation with *c-kit* ligand and mAb 29C6

Figure 3: Effect of fMLP and C5a on histamine release by human intestinal mast cells. Cells were preincubated in buffer (O, fMLP, C5a) or with c-kit ligand (KL+fMLP, KL+C5a, KL+29C6) and then stimulated with 2.5 μ M fMLP (fMLP, KL+fMLP), or 10 nM C5a (C5a, KL+C5a), or 100 ng/ml mAb 29C6 (KL+29C6). Other experimental conditions as described for Fig 1. The mean (SEM) histamine release of five (upper panel) and seven (lower panel) experiments performed in duplicate is shown. Statistical analysis (Duncan method, see text): * $p < 0.05$, ** $p < 0.01$ for a significant difference to the spontaneous release (O). Analogous results were obtained for sulphidoleukotriene production (data not shown).

($p < 0.05$) and for leukotriene production, either spontaneous release ($p < 0.05$) or after stimulation with c-kit ligand and mAb 29C6 ($p < 0.05$) or with ionomycin ($p < 0.01$). In three patients with Crohn's disease, both inflamed and macroscopically normal tissue could be obtained. Interestingly, the release reaction was much more pronounced in cells derived from inflamed areas than in cells from uninflamed areas suggesting an association between the release reaction and the activity of the disease (data not shown). In general, there was a tendency to higher release in mast cells from patients with inflammatory bowel disease compared with controls (patients with intestinal tumours or other diseases).

TABLE III Immunohistochemistry

	IBD* inflamed (n=21)	IBD uninflamed (n=21)	Controls (n=10)
Age (y)	39 (3)	38 (3)	59 (3)
Sex (m:f)	14:7	11:10	5:5
Diagnosis (CD:UC)†	10:11	10:11

c-kit positive MC (1/mm²)	57 (15)	97 (16)	71 (13)
c-kit/tryptase ratio (%)	48 (6)	55 (6)	54 (4)

*IBD=inflammatory bowel disease; †CD=Crohn's disease, UC=ulcerative colitis; ‡MC=mast cells within the lamina propria of colonic tissue. Data are presented as mean (SEM).

Expression of c-kit in intestinal tissue

Table III shows that in patients with inflammatory bowel disease the number of tryptase positive and c-kit positive lamina propria mast cells is slightly enhanced in areas of macroscopically normal mucosa compared with controls. By contrast, mast cell numbers tended to be lower in areas of active inflammation, the differences were not statistically significant (analysis of variances, $p > 0.05$). The number of tryptase positive and c-kit positive mast cells were highly correlated ($r = 0.79$, $p < 0.001$, $n = 52$), but the ratio of c-kit/tryptase positive cells did not differ between the patient groups. The histological results were almost identical in patients with Crohn's disease and ulcerative colitis (not shown).

Discussion

In this study functionally intact human mast cells were isolated from normal and pathologically changed intestinal tissue. Despite the extensive cell isolation procedure of five hours, most of the cell preparations were viable as shown by Trypan blue staining. In more than three of four experiments, histamine release could be measured, and in about one of two experiments sulphidoleukotriene production was detectable. The number of experiments, however, in which no mediators could be measured was larger than expected from similar release experiments performed with peripheral blood leucocytes.¹⁸⁻²⁰ Such negative results may be caused by low cell numbers and by the isolation procedure, which is particularly extensive and complicated for the isolation of human intestinal mast cells. Cells may be damaged during the process and the damage is not necessarily visible by classic means such as Trypan blue staining but becomes obvious in functional assays. Possibly, the rather high spontaneous release seen in this study is also a result of the isolation procedure, which may cause some kind of artificial cellular 'leakage'. Alternatively, it could be caused by an in vivo stimulation of the cells. As the spontaneous leukotriene release seems to depend on the presence of inflammation, the site of tissue resection, and the kind of disease of the donors, cell damage may be not the only reason for spontaneous release. Clearly, further studies are needed to elucidate the influence of cell isolation procedures on measurability of mast cell mediators, although the methods used here are suitable to study the regulation of mediator release by human intestinal mast cells.

It is known from previous studies that human intestinal mast cells can be stimulated in vitro for mediator release by calcium-ionophores or ionomycin and by IgE or IgE receptor crosslinking with allergen or mAb.^{12 26 27} The amount of mediators released by IgE receptor crosslinking is rather small, however, as confirmed by our findings. We found in 21 of 36 experiments (=58%) only marginal histamine release (<5% release above spontaneous release) after stimulation with a maximally effective concentration of anti-IgE receptor mAb. Similar results were

Figure 4: Correlations. (A) Number of mast cells (MC, x axis, logarithmic) versus total histamine per tube after cell lysis (y axis, logarithmic). (B) Percentage of mast cells in the cell suspensions used for the experiments (x axis, logarithmic) versus leukotriene production (LT) induced by KL and mAb 29C6 (y axis). (C) Histamine release (HR) and (D) LT induced by the mAb 29C6 without (x axis) and with (y axis) *c-kit* ligand (KL) preincubation. (E) HR and (F) LT induced by ionomycin (x axis) versus HR induced by the sequential stimulation with KL and mAb 29C6 (y axis). Experimental procedures of the release experiments and concentrations of the agonists as described in Fig 1. The number of experiments (n), the correlation coefficient (r), and the probability (p) for the hypothesis that r is distinct from zero (modified Fisher's test) are shown.

obtained for leukotriene C4 production in response to IgE receptor crosslinking. Thus, IgE receptor crosslinking in itself is a weak agonist for human intestinal mast cells in vitro. The IgE independent agonists C5a and fMLP failed to induce a significant mediator release. This is in agreement with previous studies on human intestinal and lung mast cells.^{12 16 26–28} In addition, a number of other agonists known to induce degranulation in human skin mast cells, rat peritoneal mast cells or human basophils, or all three, such as substance P, C3a, platelet activating factor, and peptides of the chemokine family, have not been tested in human intestinal mast cells but were found to be ineffective in human lung mast cells.^{16 27 28} These data show that IgE receptor crosslinking is the only known receptor dependent signal inducing mediator release in human mucosal mast cells. As it is known that mast cells can degranulate almost completely under certain in vivo conditions (for example, anaphylactic shock reactions), other, as yet unknown, factors such as cytokines should be considered, which

are more potent than IgE receptor crosslinking in activating human intestinal mast cells for mediator release, or which enhance the IgE dependent release reaction.

In this study, we selected two cytokines for examination of their capacity to regulate mediator release in human intestinal mast cells. IL 3 was selected because it is the most established growth factor for rodent mast cells and human basophil progenitors, and it primes mature human basophils for enhanced mediator release.^{1 2 18–20} *C-kit* ligand is a potent growth factor for rodent and human mast cells and a unique cytokine modulating mediator release mechanism in human lung mast cells.^{16 21} This study shows that *c-kit* ligand induces the release of small amounts of histamine and sulphidoleukotrienes in human intestinal mast cells being in the same range as the mediator release induced by IgE receptor crosslinking. Most interestingly, the sequential stimulation with *c-kit* ligand and mAb 29C6 induces a mediator release by far exceeding the effects of each agonist. Thus, *c-kit* ligand potentiates the response of intestinal mast cells towards IgE receptor dependent triggering. In particular, the release of sulphidoleukotrienes in response to mAb 29C6 is strongly enhanced by *c-kit* ligand. In *c-kit* ligand primed intestinal mast cells, anti-IgE receptor crosslinking induces the release of almost similar amounts of mediators as ionomycin. The enhancing effects of *c-kit* ligand occur within a few minutes of preincubation and seem to be independent of contaminating tissue cells, as partial purification of mast cells did not change the release reaction. Further evidence for a direct effect of *c-kit* ligand on human intestinal mast cells comes from the finding that human mast cells but not mature human basophils bear the *c-kit* ligand receptor.²⁹ These data show that *c-kit* ligand may have an important proinflammatory effect on human intestinal mast cells by strongly enhancing the IgE dependent release of preformed and de novo synthesised inflammatory mediators.

The regulation of *c-kit* ligand and its receptor in vivo is largely unknown. Human *c-kit* ligand is expressed in several cell types such as fibroblasts, endothelial cells, bone marrow stromal cells, and tumour cells, either constitutively or upon activation.^{30–32} The human *c-kit* ligand receptor, *c-kit*, was found in mast cells, basal cells of the skin, epithelial cells of the breast, a subset of natural killer cells, immature bone marrow cells, and in several tumour cells.^{32–36} Interestingly, the expression of *c-kit* on mast cells is regulated by IL 4,³⁷ a cytokine produced by T lymphocytes and mast cells, which participates in the induction of allergic immune responses.³⁸ Both *c-kit* ligand and its receptor exist in a soluble and a membrane bound form. Most probably, *c-kit* ligand, similar to other cytokines, exerts its regulatory effects in a paracrine manner, although small amounts of *c-kit* ligand (3.3 (1.1) ng/ml) are also detectable in the circulation.³⁹ At present, almost no information is available on the level and the form of expression of *c-kit* ligand in disease. It has been reported that normal

Figure 5: Mediator release in mast cells isolated from macroscopically normal (16 tumour patients, three Crohn's disease, four others) and actively inflamed (nine Crohn's disease, one ulcerative colitis) tissue. The same experiments as in Fig 1 are shown. Analogous differences in mediator release between mast cells isolated from normal and inflamed tissue were seen in experiments shown in Figs 2 and 3. Upper panel: mean of histamine release (all SEM <10%), lower panel: mean of leukotriene production (all SEM <40%). Statistical analysis (two tailed t test for independent samples): * $p < 0.05$, ** $p < 0.01$ for a significant difference between mediator release in mast cells isolated from normal and inflamed tissue.

human colon tissue does not express *c-kit*^{34 35} despite the well known presence of mast cells in the human colon mucosa and submucosa. Our data show, however, that *c-kit* is expressed in colonic tissue from patients with inflammatory bowel disease and controls. About 50% of the tryptase positive mast cells of the intestinal lamina propria stain positive for the *c-kit* ligand receptor, both in normal and actively inflamed tissue. The discrepancy between our results and previous findings may result from different *c-kit* antibodies, which are unequally suitable for immunohistochemical staining (our own finding).

In contrast with *c-kit* ligand, IL 3 failed to induce significant mediator release in itself, but preincubation with IL 3 caused an enhancement of mediator release in intestinal mast cells triggered by mAb 29C6. In comparison with *c-kit* ligand, however, the IL 3 induced enhancement was clearly weaker. This finding may be surprising as human lung mast cells do not respond to IL 3.¹⁶ It has been shown that human lung mast cells lack the IL 3 receptor,¹⁷ analogous studies with human intestinal mast cells have not yet been performed. It is probable that the enhancing effect of IL 3 is

mediated by contaminating cells such as basophils, eosinophils or monocytes bearing the high affinity IL 3 receptor. Purified mast cell preparations are needed to study the mechanism of IL 3 effect on intestinal mast cell mediator release.

The mediator release in intestinal mast cells is subjected to a large variability, which is independent of the stimulus used for cell activation. This variability may be dependent on the presence of tissue inflammation, the kind of disease the donor suffers from, and yet unknown genetic factors. In this study, data from different patients were pooled together, which surely augment the variability. For example, Fig 5 shows that the presence of tissue inflammation in patients with inflammatory bowel disease is a relevant factor for the outcome of the release reaction. Previous studies showed, however, that a considerable variability of mediator release can be seen even in healthy persons. The phenomenon, which has been termed 'releasability', has been extensively studied in human basophils (reviewed in ref 3). The mechanism of releasability and the factors influencing it (in vivo priming by cytokines, genetic factors?) have not yet been clearly defined. Statistical analysis of data becomes difficult for such reasons, particularly, if tests for comparison of multiple means (analysis of variances) not reflecting paired data are used. The fact that nevertheless statistically significant differences were found between patients with inflammatory bowel disease and controls emphasises the potential role of mast cells in the pathogenesis of chronic intestinal inflammation.

Our data suggest that the spontaneous and the induced release of histamine and in particular of leukotrienes is enhanced in mast cells isolated from actively inflamed tissues from patients with inflammatory bowel disease (most of them with Crohn's disease) compared with the release in mast cells isolated from macroscopically normal tissue derived from tumour patients. Particularly, the inducible release of leukotrienes was considerably lower in mast cells derived from uninflamed Crohn's tissue than in mast cells from inflamed Crohn's tissue. These findings extend the findings by Knutson *et al*¹⁰ who showed an increased spontaneous histamine secretion rate in vivo in patients with active Crohn's disease, and suggested that mast cell activation participates in Crohn's disease. More recently, Casellas *et al*¹¹ found an increased intraluminal secretion of LTC₄ in Crohn's disease patients showing that our in vitro findings are indeed of relevance in vivo. The in vitro release of mast cell mediators in patients with inflammatory bowel disease has been examined in two studies. Sanderson *et al*⁴⁰ reported no difference in histamine release from biopsy specimens of inflamed tissue derived from children with Crohn's disease. By contrast Fox *et al*¹² found that release of preformed histamine and newly synthesised lipid mediators induced by IgE crosslinking was enhanced in mast cells isolated from actively inflamed tissue derived from patients with ulcerative colitis compared

with control tissue. The mechanism of enhanced mediator release in patients with inflammatory bowel disease is unclear. It may be speculated that increased expression of *c-kit* or *c-kit* ligand may be involved. Our data show that the portion of *c-kit* positive mast cells in the lamina propria is similar in patients with and without active inflammation and in controls. It has not yet been examined whether *c-kit* ligand synthesis is increased in areas of active inflammation in the course of inflammatory bowel disease.

Mast cells and their mediators have been associated with a number of gastrointestinal diseases such as food hypersensitivity, inflammatory bowel disease, coeliac disease, chronic idiopathic diarrhoea, motility disorders, and helminth infections.⁷⁻¹⁴ These disorders have in common that their aetiology or pathophysiology, or both, is largely unclear. Because of the well defined role of mast cell in allergic reactions, it is obvious that mast cells participate in the pathogenesis of intestinal hypersensitivity reactions.^{7,41-43} It is tempting to speculate that mast cells are also of importance in other inflammatory diseases of the intestine. It is questionable, however, whether such diseases are always IgE dependent. The definition of IgE independent mast cell agonists such as *c-kit* ligand or the recently described epithelial cell derived proteins⁴⁴ capable of triggering mast cells for mediator release or enhancing the release reaction induced by other secretagogues may be of particular relevance for these disorders. Therefore, further studies are necessary to examine the expression of *c-kit* ligand and its receptor in disease, and to correlate these data with the in vivo release of mast cell mediators.

This work was supported by the Deutsche Forschungsgemeinschaft (SFB 280-C8). The authors thank Drs R Chizzonite and J P Kochan (Hoffmann-La Roche, Nutley, NJ) for providing the mAb 29C6; Drs H W Lahm and H Langen (Hoffmann-La Roche, Basle, Switzerland), Drs M Schreier and E Liehl (Sandoz Ltd, Basle, Switzerland and Vienna, Austria), and Amgen Inc (Thousand Oaks, CA) for gifts of cytokines.
