Pouchitis after ileal pouch-anal anastomosis for ulcerative colitis occurs with increased frequency in patients with associated primary sclerosing cholangitis

Abstract

Primary sclerosing cholangitis (PSC), present in 5% of patients with ulcerative colitis, may be associated with pouchitis after ileal pouch-anal anastomosis. The cumulative frequency of pouchitis in patients with and without PSC who underwent ileal pouch-anal anastomosis for ulcerative colitis was determined. A total of 1097 patients who had an ileal pouch-anal anastomosis for ulcerative colitis, 54 with associated PSC, were studied. Pouchitis was defined by clinical criteria in all patients and by clinical, endoscopic, and histological criteria in 83% of PSC patients and 85% of their matched controls. PSC was defined by clinical, radiological, and pathological findings. One or more episodes of pouchitis occurred in 32% of patients without PSC and 63% of patients with PSC. The cumulative risk of pouchitis at one, two, five, and 10 years after ileal pouch-anal anastomosis was 15.5%, 22.5%, 36%, and 45.5% for the patients without PSC and 22%, 43%, 61%, and 79% for the patients with PSC. In the PSC group, the risk of pouchitis was not related to the severity of liver disease. In conclusion, the strong correlation between PSC and pouchitis suggest a common link in their pathogenesis.

Keywords: pouchitis, ulcerative colitis, primary sclerosing cholangitis.

Restorative proctocolectomy with ileal reservoir is now a widely accepted procedure in the surgical treatment of ulcerative colitis (UC). The operation cures the gastrointestinal symptoms and eliminates the potential for malignant degeneration while preserving anorectal functions.

Non-specific inflammation of the reservoir or pouchitis is the principal longterm complication of ileal pouch-anal anastomosis (IPAA). The clinical problem, dominated by diarrhoea, sometimes containing blood, and abdominal discomfort, varies between 7 and 47% of patients depending on the duration of follow up. Pouchitis usually occurs in patients operated on for UC and has been associated with the presence of extraintestinal manifestations of the disease. In particular, the presence of concomitant primary sclerosing cholangitis (PSC), a chronic cholestatic syndrome of unknown cause characterised by fibrosing obliteration of the bile ducts, seems to be a significant risk factor for the development of pouchitis.

To further explore the association between PSC and pouchitis, the aims of this study were: (a) to determine if PSC represents an independent risk factor for pouchitis; (b) to compare clinical, endoscopic, and pathological findings of pouchitis in a subset of patients without PSC; and (c) to search for correlations between the risk of pouchitis and status of liver disease.

Methods

Patients

Between January 1981 and April 1993, 1097 patients underwent ileal J pouch-anal anastomosis for UC at the Mayo Medical Center in Rochester, Minnesota. All pouches were constructed according to a technique previously described, and patients with indeterminate colitis or with other designs of reservoir were excluded. The following information was retrieved from the medical records of all patients: duration of UC calculated from the date of onset of colonic symptoms to the date of IPAA; extent of UC (rectal, sigmoid, left sided, and pancolonic) and indication for IPAA.

Fifty four of these patients were identified as having associated PSC. The diagnosis of PSC was based on established clinical or biochemical evidence of cholestasis of more than six months’ duration and characteristic cholangiographic or typical hepatic histological findings, or both. For those patients with PSC, the following information was retrieved from the medical record: (1) Duration of PSC determined by the date of earliest suggested evidence of liver disease. (2) Specific symptoms and signs of liver disease, such as jaundice, fever, cholangitis, encephalopathy, variceal bleeding, ascites, hepatomegaly, splenomegaly, and oesophageal varices. (3) Biochemical testing, including serum alkaline phosphatase, total bilirubin, aspartate aminotransferase, prothrombin time, and serum protein electrophoresis. (4) Cholangiographic appearance of the biliary tree was classified as normal, extrahepatic changes, or intra and extrahepatic changes. Small duct PSC was
defined as histological evidence of PSC (pericholangitis) with a normal cholangiogram in a patient with a history of UC. Histological changes were classified according to the criteria of Ludwig et al13: cholangitis or portal hepatitis (stage I), periportal fibrosis or perportal hepatitis (stage II), septal fibrosis or bridging necrosis, or both (stage III), and biliary cirrhosis (stage IV). Likelihood of patient survival (with regard to PSC) was based on serum bilirubin concentration, histological stage on liver biopsy, age, and the presence of splenomegaly14 was also determined for each patient.

Definition of pouchitis and classification of clinical course
The diagnosis of pouchitis was based on clinical criteria including watery diarrhoea, haematochezia, urgency, abdominal or pelvic discomfort, malaise, and fever. The occurrence of pouchitis in patients with or without PSC was determined by the date of the first episode after IPAA retrieved from a computerised registry. This registry was also used to determine the length of time between IPAA and the first episode of pouchitis, the symptoms of pouchitis, and the number of episodes of pouchitis (less than or equal to two, more than two, or chronic pouchitis).

A more detailed comparison of the clinical, endoscopic, and histological features of all the patients with pouchitis and PSC (n=34) were compared with a group of patients with pouchitis but without PSC (n=33) retrieved from the computerised registry and matched for age, sex, extraintestinal manifestations other than PSC, date of IPAA, and length of follow up after closure of the temporary ileostomy. This more detailed evaluation was performed to assess whether the severity of pouchitis was similar in patients with and without PSC. Clinical evaluation included the length of time between IPAA and the first episode of pouchitis, the symptoms of pouchitis, and the number of episodes of pouchitis as defined above. The following endoscopic findings of inflammation were recorded as present or absent: oedema; granularity; friability; erythema; loss of the vascular pattern; mucus exudate; and mucosal ulceration.15 16 The severity of endoscopic inflammation was then classified according to the following definition: mild (discrete oedema of the mucosa); moderate (erythema, mucopurulent exudate, and small ulcerations); or severe (deep ulcerations, diffuse erythema, and extensive mucosal necrosis). Histopathological changes were classified according to the criteria of Shepherd et al.16 17 The pouchitis disease activity index as described by Sandborn18 was also used to quantify pouchitis disease severity.

Bowel function was obtained from the registry annually updated by a clinical nurse coordinator using telephone contact or questionnaire mailings, or both. Incontinence was described as none, occasional (no interruption of daily activities), or frequent (more than one episode per week with interruption of activities). The use of drugs was defined by the need for more than four days per week of anti-diarrhoeal agents or antibiotics to control the frequency of defecation.

Statistical methods
The association of pouchitis with nominal risk factors was assessed with χ² tests, the association with ordinal risk factors was assessed with rank sum tests, and the association with continuous variables was assessed with t tests or, when necessary, rank sum tests. The occurrence of pouchitis was estimated as a function of time since surgery using the Kaplan-Meier method. Log rank tests were used to compare the curves with nominal risk factors.

Results
Cumulative risk of pouchitis after IPAA in UC with or without PSC
Overall, pouchitis occurred at least once in 370 patients (35.7%) after IPAA. Among the 1043 patients without PSC, pouchitis occurred in 336 patients (32%) and in 34 of 54 patients with associated PSC (63%) (p<0.001, χ²). The estimated risk of pouchitis at one, two, five, and 10 years after IPAA was 15.5%, 22.5%, 36%, and 45.5%, respectively, in patients without PSC; and 22%, 43%, 61%, and 79% in patients with PSC, respectively. Figure 1 shows the occurrence of pouchitis estimated as a function of time. The risk was significantly greater in PSC patients (p<0.0001, log rank).

Pouchitis disease course after IPAA for UC with and without PSC
Chronic pouchitis was more frequent in the group of patients with PSC (60% v 15%, p<0.001), and acute pouchitis in those patients with less than or equal to two episodes, occurred more often in patients without PSC (36% v 6%, p<0.001) (Fig 2).

Clinical, endoscopic, and histological presentation of pouchitis in 34 patients with PSC (group 1) were compared with a group of 33 matched UC patients without PSC (group 2). As Table I shows, both groups were comparable with regard to demographic characteristics.

The mean interval between ileostomy closure and the occurrence of the first episode of pouchitis was 12 months (range one to 96 months) in group 1 and 13 months (range two to 60 months) in group 2 (p=0.8). Diarrhoea was the most common symptom and was present in 94 and 97% of each group respectively. Abdominal cramping (79% v 44%, p=0.004) and bloody stools (39% v 17%, p=0.048) were more frequent in group 1.

Endoscopic examination of the reservoir during or immediately after an episode of pouchitis was performed in 28 patients (83%) in group 1 and 28 patients (85%) in group 2. Pouch endoscopy showed similar patterns.
The histological score was determined for 28 patients (83%) in group 1 and 28 patients (85%) in group 2. Only 50% (14 of 28) of patients with PSC (group 1) and 43% (12 patients) of patients without PSC (group 2) had a histological score of acute inflammation equal to or superior to 4 and a histological score of chronic inflammation equal to or superior to 4. The mean overall histological score was 5·6 (1·3) in group 1 and 5·4 (1·2) in group 2 (p=0·47). The pouchitis disease activity index (PDAI) score was greater than or equal to 7 in 93% of patients in group 1 and 96% of patients in group 2, and the mean PDAI score was 8·8 (1·6) in group 1 and 9·1 (2) in group 2 (p=0·8).

Figure 2: Pouchitis disease course after IPAA in patients with and without PSC.

Bowel function after IPAA in pouchitis patients with or without PSC was comparable (Table II); however, more patients in the PSC group had nocturnal stooling, daytime incontinence, and needed drugs.

The characteristics of patients with pouchitis (PSC) and group 2 (no PSC) are listed in Table I.

Table I: Characteristics of patients with pouchitis 1 group 1 (PSC) and group 2 (no PSC)

PSC features and bowel function in PSC patients with and without pouchitis

Among the 54 patients with PSC, 34 developed pouchitis after IPAA (group A, mean follow up 62·5 months, range 12 to 144) and 20 patients did not (group B, mean follow up 65 months, range six to 204). There was no difference between the two groups in terms of sex (male to female ratio 17:17 in group A and 11:9 in group B, p=0·8), age at the diagnosis of UC (20·5 (6) years v 25 (10) years, p=0·8), presence of pancolonic disease (33 of 34 v 20 of 20, p=0·8), age at time of IPAA (31 (18) years v 40 (9) years, p=0·3), or presence of extraintestinal manifestations other than PSC (six of 34 v four of 20, p=0·6). The mean (SD) age at the diagnosis of PSC was 30 (8) years (range 14 to 46) in patients with pouchitis and 39 (10) years (range 17 to 52) in patients without pouchitis (p=0·001).

As Table II shows, the occurrence of PSC in pouchitis patients did not influence stool frequency or continence. The use of anti-diarrhoeal drugs was no greater in patients who experienced pouchitis than in those who did not.

A similar number of patients in each group presented symptoms of liver disease (10 of 34 in group A v eight of 20 in group B, p=0·4) and signs of liver disease (nine of 34 v three of 20 for groups A and B, respectively, p=0·3). However, splenomegaly (24% v 10%) and oesophageal varices (20% v 10%) were more frequent in patients with pouchitis.

Table III shows that mean values of biochemical tests were similar in both groups.

Cholangiograms were performed in 46 of the patients diagnosed with PSC. Of these, 10 (22%) had small duct PSC, one (2%) had only extrahepatic involvement, and 35 (76%) had evidence of extra and intrahepatic involvement of the biliary tree. Only three of 10 patients with small duct PSC developed pouchitis (30%), while 23 of 35 patients with total involvement of the biliary tree subsequently had pouchitis (66%) (p=0·01).

Liver biopsy specimens were obtained in 28 patients with pouchitis and 19 patients without pouchitis. Overall, there were 10 stage I, 20 stage II, six stage III, and 11 stage IV. In the
group with pouchitis, 15 patients (54%) had early hepatic changes (stages I and II) compared with 15 patients (79%) in the group without pouchitis \( (p=0.3) \). Late changes (stages III and IV) were present in 13 patients with pouchitis (46%) and in four patients without pouchitis (21%) \( (p=0.3) \).

A risk score could be calculated in 48 patients. The mean (SD) score was 2.79 (1) in the group with pouchitis and 2.73 (0.9) in the group without pouchitis \( (p=0.8, \log \text{rank}) \). At follow up, six patients with PSC had died, three each with and without pouchitis, a mean of 54 months after the IPAA and 64 months after the diagnosis of PSC. The estimated survival five years after the diagnosis of PSC was 80%. Cause of death included cholangiocarcinoma in two patients, liver cirrhosis in one patient, and metastatic colon cancer in one patient. Eight patients underwent orthotopic liver transplantation for end stage liver disease and have been described in detail elsewhere.19

Discussion
Our findings show that patients with both UC and PSC have an increased risk of pouchitis after IPAA. Clinical symptoms of inflammation of the pouch occurred in 64% of 54 patients with PSC and in 32% of 1043 patients without PSC. Moreover, chronic pouchitis defined by the need for drugs (antibiotics/anti-inflammatory drugs) more than 15 days per month to control symptoms was significantly more frequent in the group of patients with PSC. Endoscopic and histological presentation of pouchitis were similar in both groups of patients. We did not find any significant correlation between the severity of the liver disease and the risk of pouchitis in the group of patients with PSC; however, pouchitis was more frequent in patients with diffuse changes on endoscopic retrograde cholangiopancreatoscopy (ERCP) (large duct PSC) and in patients with stage III and IV disease on liver biopsies.

IPAA is a widely accepted procedure for the surgical treatment of ulcerative colitis as 94% of patients have a successful outcome over the long term.2 As experience with this technique has grown, however, it has become evident that acute pouch inflammation or pouchitis is becoming an important long-term complication. Even with rapid response to treatment, 13% of all IPAA patients regard pouchitis to be a significant chronic problem with social and professional inconvenience.6

The highly variable frequency of pouchitis in published series may be explained by the variety of diagnostic criteria used to define this syndrome and the extent of follow up. In the past, the diagnosis of pouchitis was based solely upon the clinical presentation,2 5 6 Some authors have advocated the use of endoscopic13 or histological criteria16 17 to confirm a clinical diagnosis of pouchitis. In general, we agree with this approach.18 20 This viewpoint has not been widely adopted until recently, however, and many of our patients who have been given a clinical diagnosis of pouchitis have not been treated with biopsies. In this study, we used clinical criteria to diagnose pouchitis in all 1097 patients. There is some concern that the failure to confirm a clinical diagnosis of pouchitis with endoscopy and histology may lead to an overestimation of the frequency of pouchitis by including patients with irritable bowel syndrome, Crohn’s disease, and anastomotic stricture.18 This criticism may apply to our patients with a clinical diagnosis of pouchitis who do not have PSC, many of whom did not have a confirmatory endoscopy with biopsies. Most (83%) of our patients with PSC and pouchitis, however, had the clinical diagnosis confirmed endoscopically and histologically, making an overestimation of pouchitis in this group unlikely. If the frequency of pouchitis is overestimated in patients without PSC but not in patients with PSC, the net effect would be to decrease the difference in the frequency of pouchitis between the two groups. Thus, the highly significant difference in the frequency of pouchitis between patients with and without PSC in our study may represent a minimal estimate. Based on these data, we believe that the association between PSC and pouchitis is real.

IPAA is a widely accepted procedure for the surgical treatment of ulcerative colitis as 94% of patients have a successful outcome over the long term.2 As experience with this technique has grown, however, it has become evident that acute pouch inflammation or pouchitis is becoming an important long-term complication. Even with rapid response to treatment, 13% of all IPAA patients regard pouchitis to be a significant chronic problem with social and professional inconvenience.6

The highly variable frequency of pouchitis in published series may be explained by the variety of diagnostic criteria used to define this syndrome and the extent of follow up. In the past, the diagnosis of pouchitis was based solely upon the clinical presentation,2 5 6 Some authors have advocated the use of endoscopic13 or histological criteria16 17 to confirm a clinical diagnosis of pouchitis. In general, we agree with this approach.18 20 This viewpoint has not been widely adopted until recently, however, and many of our patients who have been given a clinical diagnosis of pouchitis have not been treated with biopsies. In this study, we used clinical criteria to diagnose pouchitis in all 1097 patients. There is some concern that the failure to confirm a clinical diagnosis of pouchitis with endoscopy and histology may lead to an overestimation of the frequency of pouchitis by including patients with irritable bowel syndrome, Crohn’s disease, and anastomotic stricture.18 This criticism may apply to our patients with a clinical diagnosis of pouchitis who do not have PSC, many of whom did not have a confirmatory endoscopy with biopsies. Most (83%) of our patients with PSC and pouchitis, however, had the clinical diagnosis confirmed endoscopically and histologically, making an overestimation of pouchitis in this group unlikely. If the frequency of pouchitis is overestimated in patients without PSC but not in patients with PSC, the net effect would be to decrease the difference in the frequency of pouchitis between the two groups. Thus, the highly significant difference in the frequency of pouchitis between patients with and without PSC in our study may represent a minimal estimate. Based on these data, we believe that the association between PSC and pouchitis is real.

In patients with pouchitis and PSC, and matched controls with pouchitis but without PSC, we found that the use of histological criterion16 17 alone to diagnose pouchitis was inaccurate in nearly 50% of patients. This may be explained by a lack of sensitivity and specificity for histological examination.18 Pouch inflammation is often patchy and random biopsy specimens may show a great variation of the severity of inflammation within the pouch. Chronic inflammatory changes in the pouch are almost universal,14 and some degree of acute inflammation is present in 38% to 64% of pouches.16 21 On the other hand, some inflamed pouches with clinical symptoms and endoscopic changes of acute inflammation may fail to show a histological score of inflammation greater than 8 and therefore may not be classified as pouchitis based on histological criteria alone. The PDAI18 may be a better
indicator of pouchitis. Although this index has not yet been validated, it does seem to be useful in distinguishing patients with and without pouchitis. After a clinical diagnosis of pouchitis has been confirmed with endoscopy and histology, clinical criteria alone may be sufficient for patient treatment as a correlation between the two modes of diagnosis was found in more than 90% of patients in this study.

The aetiology of pouchitis remains unclear; proposed mechanisms include faecal stasis, perturbation of bacterial flora in the pouch, nutritional deficiencies, ischaemia, and recurrence of UC within the pouch. Identifying clinical risk factors for pouchitis may help elucidate the aetiology of this disorder. Clinical findings favouring the recurrent UC theory include: the low frequency of pouchitis in patients with familial polyposis and an IPAA; the association of pouchitis with the extraintestinal manifestations of UC; and the association of perinuclear antineutrophil cytoplasmic antibodies (pANCA) with UC, PSC, and chronic pouchitis. This study strengthens the recurrent UC theory by showing a strong association between pouchitis and a specific extraintestinal manifestation of UC, PSC. We did not determine the pANCA status of the 1097 patients in this study; however, further study of the inter-relation of pANCA and pouchitis in UC patients with and without PSC certainly seems warranted in further studies. Likewise, studies to determine the HLA genotypes of these patient subgroups should be undertaken.

A high faecal bile acid pool in patients with PSC could also potentially contribute to the development of pouchitis. In UC patients with an IPAA, there seems to be no difference in the total concentration or total daily output of faecal bile acids between those with and without pouchitis. There is some disagreement, however, as to whether bile acid conjugation and dehydroxylation is increased, unchanged or decreased compared with patients without pouchitis. To date, there are no published reports that bile acids are different in patients with PSC. We did not specifically inquire about the use of ursodeoxycholic acid as a treatment for PSC or the use of cholestyramine as a treatment for pruritus associated with PSC, although it is probable that some of the patients with PSC were taking these drugs. We have previously shown that ursodeoxycholic acid does not improve the disease course of UC in patients with PSC, and we believed it unlikely to affect the disease course of pouchitis. There was not a correlation between the histological stage of liver disease (stage III or IV) and the development of pouchitis. Thus, treatment with cholestyramine would be unlikely to affect the development of course of pouchitis. The absence of correlation between the risk score of PSC or the histological stage of PSC and the risk of pouchitis lead us to think that the occurrence of pouchitis in PSC patients is dependent upon factors other than the severity of hepatobiliary involvement. Of interest, the risk of pouchitis was greater in patients with diffuse involvement of the biliary tree (66%) than in patients with small duct PSC (30%).

Despite the risk of pouchitis and an increased risk of postoperative complications, IPAA is still our preferred surgical treatment for patients presenting with UC and PSC. After proctocolectomy and Brooke ileostomy, we have performed ileostomy reversal in more than 90% of patients within four years and are often associated with troublesome bleeding. IPAA can be performed safely in patients with PSC and, thus far, there is no risk of ileoanal anastomotic varices and bleeding. The high incidence of chronic pouchitis clearly emphasises the need for better treatments; however, this major cause of concern after IPAA seldom requires pouch exclusion or diversion.

The authors thank Lorraine Winter for her meticulous record keeping and Jenny Walsh for the preparation of this manuscript. Presented in part at the Annual Meeting of the American Gastroenterology Association, New Orleans, 1994 and published as an abstract in Gastroenterology 1994; 106: A751.
