Lactobacillus acidophilus (strain LB) from the resident adult human gastrointestinal microflora exerts activity against brush border damage promoted by a diarrhoeagenic Escherichia coli in human enterocyte-like cells

V Liévin-Le Moal, R Amsellem, A L Servin, M-H Coconnier

Background and aims: The normal gastrointestinal microflora exerts a barrier effect against enteropathogens. The aim of this study was to examine whether lactobacilli, a minor genus of the resident gut microflora, exerts a protective effect against the cellular injuries promoted by the diarrhoeagenic Afa/Dr diffusely adhering Escherichia coli (Afa/Dr DAEC) C1845 strain in human intestinal cells.

Methods: Cultured human intestinal fully differentiated enterocyte-like Caco-2/TC7 cells were used. Antibacterial activity was examined by measuring the viability of the adhering C1845 bacteria. The distribution of brush border associated cytoskeleton and functional proteins was examined by immunofluorescence labelling coupled to confocal laser scanning microscopy analysis.

Results: The activity of Lactobacillus acidophilus strain LB isolated from the resident human gastrointestinal microflora was examined. A dose dependent decrease in viability of C1845 bacteria was observed after both direct contact in vitro between the spent culture supernatant (LB-SCS) and the bacteria and when the bacteria were adherent on Caco-2/TC7 cells. Protection against the C1845 induced alterations in expression of F-actin, sucrase-isomaltase, dipeptidylpeptidase IV, alkaline phosphatase, and fructose transporter alterations was observed when the cells were exposed to LB-SCS.

Conclusion: L acidophilus strain isolated from the resident adult human gastrointestinal microflora, together with its antimicrobial activity, exerts a protective effect against the brush border lesions promoted by the diarrhoeagenic Afa/Dr DAEC strain C1845.

Knowledge of the predominant genera and species of the gastrointestinal microflora as well as determination of their levels and biochemical activities are essential in the understanding of the microbial ecology of the gastrointestinal tract. The normal resident gastrointestinal microflora contains many diverse populations of bacteria which play an essential role in the development and well being of the host. Moreover, commensal bacteria changes a specific glycosylation process in cultured human intestinal cells.

During the past 10 years, evidence has accumulated in support of a non-immune system of defence in the intestine. By continual release of antibiotic proteins, resident bacteria of the human microflora could exert a protective role against entero-virulent pathogen induced cellular damage, we have chosen to examine the activity of a Lactobacillus acidophilus strain isolated from the resident adult human microflora for which the production of secreted antimicrobial substances has been well established both in vitro and in vivo. As an entero-virulent pathogen producing cellular damage in enterocytes, we have chosen the diarrhoeagenic wild-type Afa/Dr diffusely adhering E. coli (DAEC) C1845 strain. Epidemiological studies have established a link between Afa/Dr DAEC and persistent diarrhoeal diseases, mostly in infants older than 24 months.

Colonisation of the intestine by these pathogenic E. coli is mediated by their harbouring Afa/Dr adhesins. All of these adhesins mediate diffuse adhesion onto human epithelial intestinal cells and recognise as a receptor the decay accelerating factor (or CD55) by interacting with the short consensus repeat 2 and 3 domains of the molecule. We have recently demonstrated that after attachment onto intestinal brush border some members of this family of E. coli promoted microvillus (MV) injury. These MV lesions resulted from apical cytoskeleton

Abbreviations: MV, microvillus; SI, sucrase-isomaltase; DPP IV, dipeptidylpeptidase IV; GR, glycosylphosphatidylinositol; AP, alkaline phosphatase; TRITC, tetramethyl rhodamine isothiocyanate; FITC, fluorescein isothiocyanate; MRS broth, De Man, Rogosa, Sharpe broth; SCS, spent culture supernatant; TSA, tryptic soy agar; PBS, phosphate buffered saline; LDH, lactate dehydrogenase; cIc, colony forming units; CLSM, confocal laser scanning microscopy; DMEM, Dulbecco’s minimal essential medium.
disassembly that follows activation of the CD55 molecule by Afa/Dr adhesins and subsequent Ca\(^{2+}\) dependent signalling.\(^{26}\) These structural lesions were accompanied by a dramatic alteration in the brush border expression of functional intestinal proteins such as hydrolases and transporters that play a pivotal role in intestinal function.\(^{37}\) As a cellular model, we have chosen the human colon adenocarcinoma cell line Caco-2,\(^{21}\) one of the human intestinal models most commonly used to study in vitro expression of intestine specific functional proteins.\(^{23}\) We have focused our study on the structural brush border associated protein F-actin, and brush border associated functional proteins, namely the hydrolases sucrase-isomaltase (SI) (EC 3.2.1.48–10) and dipeptidylpeptidase IV (DPP IV) (EC 3.4.14.5), the glycosylphosphatidylinositol (GPI) anchored protein alkaline phosphatase (AP), and the fructose transporter GLUT5.

**MATERIALS AND METHODS**

**Reagents and antibodies**

Fluorescein labelled phalloidin was from Molecular Probes (Junction City, Oregon, USA). BAPTA/AM (1,2-bis[2-aminophenoxy]ethane-N,N,N′,N′-tetraacetic acid tetrakis[acetoxy-methyl] ester) was obtained from Sigma-Aldrich Chimie SARL (L’Isle d’Abeau Chesnes, France).

Polyclonal rabbit anti-Dr adhesin antibody was a gift from B1 Nowicki (Texas University, Galveston, Texas, USA). The monoclonal antibodies antihuman SI (8A9) and anti-DPP IV (4H3) were a gift from S Maroux (ESA 6033 CNRS, Marseille, France). The rabbit polyclonal antibody directed against the fructose transporter GLUT 5 was kindly provided by E Brot-Laroche (INSERM U505, Paris, France). The rabbit polyclonal antibody directed against AP was from Dako (Tebu, Paris, France). The appropriate tetramethyl rhodamine isothiocyanate (TRITC) conjugated and fluorescein isothiocyanate (FITC) conjugated secondary antibodies were obtained from Boehringer and Immunoresearch ICN Laboratory and were diluted 1:20 to 1:200 in 0.2% gelatin-phosphate buffered saline (PBS).

**Bacterial strains and growth conditions**

The clinical isolate Afa/Dr DAEC C1845 strain harbouring the fimbrial F1845\(^{23}\) was grown at 37°C for 18 hours in Luria broth. L. acidophilus LB strain was isolated from a human stool (Lacteol Laboratory, Houdan, France).\(^{14,17}\) LB bacteria were grown in De Man, Rogosa, Sharpe (MRS) broth (Biokar Diagnostics, Beauvais, France) for 18 hours at 37°C. Cultured supernatant of LB (LB-SCS) was obtained by centrifugation at 10 000 \(\times\) g for 30 minutes. Centrifuged LB-SCS was passed through a sterile 0.22 \(\mu\)m filter unit (Millex GS; Millipore, Bedford, MA). Filtered LB-SCS was assessed for the presence of bacterial colonies by plating on tryptic soy agar (TSA). A concentrated LB-SCS was obtained by freeze drying.

**Cell culture**

The low glucose consuming Caco-2/TC7 clone (Caco-2/TC7),\(^{26}\) established from the parental Caco-2 cell line,\(^{27}\) was used. This clone was similar to parental Caco-2 cells in terms of cell polarity and displayed an apical brush border endowed with brush border associated functional proteins, namely the hydrolases sucrase-isomaltase (SI) (EC 3.2.1.48–10) and dipeptidylpeptidase IV (DPP IV) (EC 3.4.14.5), the glycosylphosphatidylinositol (GPI) anchored protein alkaline phosphatase (AP), and the fructose transporter GLUT5.

**Cell infection**

The Caco-2/TC7-7 monolayers were prepared in 24 well TPP tissue culture plates (ATGC, Paris, France). A cell infection assay was conducted as previously reported.\(^{22}\) Briefly, prior to infection, the cell monolayers were washed twice with PBS. C1845 bacteria suspended in the culture medium were added to each well of the tissue culture plate. The infection assay was conducted in the presence of 1% mannose to prevent type 1 fimbriae mediated binding. The plates were incubated at 37°C in 10% CO\(_2\)/90% air for three hours and washed three times with sterile PBS.

**Electron microscopy**

For transmission electron microscopy, cells were rinsed three times with PBS, and fixed with 2.5% glutaraldehyde in 0.1 M sodium phosphate buffer (pH 7.4) for 30 minutes at room temperature. After washing with PBS, cells were postfixed for 30 minutes at room temperature with 1.5% osmium tetroxide in sodium phosphate buffer. Filters were then dehydrated in graded ethanol series, cut into strips, and embedded in epoxy resin. Ultrathin sections were cut from transversely orientated confluent monolayers. Ultrathin sections were double stained with uranyl acetate and lead citrate and examined with a Jeol JEM-1010 electron microscope.

**Measurement of cell integrity**

Cell integrity was determined by measuring lactate dehydrogenase (LDH) activity in the apical compartment of filter grown cells (Enzyline LDH kit; Biomérieux, Dardilly, France) according to the manufacturer’s instructions.

**Determination of antimicrobial activity**

Antimicrobial activity of LB-SCS in vitro was examined as previously described.\(^{23,24}\) As indicator strain, the Afa/Dr DAEC C1845 strain was grown overnight for 18 hours at 37°C in Luria broth. Bacteria were centrifuged at 5500 \(\times\) g for five minutes at 4°C, washed once with PBS, and resuspended in PBS. C1845 bacteria were counted and a volume containing 10\(^{6}\) colony forming units (cfu)/ml was used to determine the activity of LB-SCS. Colony count assays were performed by incubating 1 ml of PBS containing C1845 bacteria (10\(^{6}\) cfu/ml) with 1 ml of LB-SCS at 37°C. At predetermined intervals, aliquots were removed, serially diluted, and plated on TSA to determine bacterial colony counts numbers.

In a second protocol, activity was determined in Caco-2/TC7 cells (10\(^{6}\) cfu/ml) infected for three hours with C1845 bacteria. Infected cell monolayers were washed twice with sterile PBS to remove non-adhering bacteria and subjected to LB-SCS treatment for one hour at 37°C. To determine the viable cell associated C1845 bacteria, the infected cell monolayers were lysed by adding H\(_2\)O\(_2\). Appropriate dilutions were plated on TSA to determine the number of viable cell associated bacteria by bacterial colony counts.

**Immunofluorescence**

Monolayers of Caco-2/TC7 cells were prepared on glass cover-slips which were placed in 24 well TPP tissue culture plates. After infection, cell preparations were fixed for 15 minutes at room temperature in PBS-3% paraformaldehyde. They were washed three times with PBS and then treated with 50 mM NH\(_4\)Cl for 10 minutes for aldehyde function saturation. Examination of F-actin was conducted by direct immunofluorescence labelling using fluorescein labelled phalloidin, as previously described.\(^{21}\) The coverslips were incubated for four minutes with PBS-0.2% Triton X-100 before incubation with fluorescein labelled phalloidin for 45 minutes at 22°C, after which the coverslips were washed three times with PBS. Indirect immunolabelling of brush border associated SI, DPP IV, and AP was conducted with or without cell permeabilisation, as previously described.\(^{22}\) The monoclonal antibodies were obtained from Sigma-Aldrich Chimie SARL (L’Isle d’Abeau Chesnes, France). Filtered LB-SCS was assessed for the presence of bacterial colonies by plating on tryptic soy agar (TSA). A concentrated LB-SCS was obtained by freeze drying.
anti-SI 8A9 and anti-DPP IV 4H3 were diluted 1:200 and 1:50, respectively, in 0.2% gelatin-PBS. Polyclonal anti-AP antibody was diluted 1:20 in 0.2% gelatin-PBS. GLUT5 immunolabeling was conducted in Triton X-100 (0.2%) permeabilised cells.21 Polyclonal anti-GLUT5 was diluted 1:500 in 0.2% gelatin-PBS. Fixed monolayers were incubated with the primary antibody for 45 minutes at room temperature. After three washes in PBS, incubation with an FITC or TRITC conjugated secondary antibody (diluted 1:50 in PBS) was performed for 45 minutes at room temperature. After three washes, cells were mounted with VECTashield (Biosys SA, Compiègne, France) for immunofluorescence examination. No fluorescent staining was observed when the primary antibody was omitted.

For examination of adhering C1845 bacteria onto Caco-2/TC7 cells, indirect immunofluorescence microscopy was performed with a polyclonal antibody directed against Dr adhesin. Coverslips were incubated with primary antibody (diluted 1:100 in 0.2% gelatin-PBS) for 45 minutes at 22°C, washed three times with PBS, and then incubated with an FITC secondary antibody (diluted 1:50 in PBS) for 45 minutes at 22°C. The coverslips were then washed three times with PBS.

Specimens were mounted in Vectashield mounting medium (Vector Laboratory, Burlingame, California, USA). Specimens were examined by conventional epifluorescence microscopy using a Leitz Aristoplan microscope coupled to an Image Analyser Visiolab 1000 (Biocam, Les Ulis, France). Relative immunofluorescence intensity was measured and results expressed as arbitrary units. A confocal analysis was conducted using a confocal laser scanning microscope (CLSM) (model LSM 510 Zeiss, equipped with an air cooled argon ion laser 488 nm, and a helium neon laser 543 nm) configured with an Axiovert 100M microscope using a Plan Apochromat 63X/1.40 oil objective. Optical sectioning was used to collect 50 en face images 1 µm apart. Lateral views were obtained by integration of the images gathered at a step position of 1 on the x–y axis using the accompanying Zeiss software LSM510. 2.5 on Windows NT4. Photographic images were resized, organised, and labelled using Adobe Photoshop software (San Jose, California, USA). The printed images (Kodak XLS 8600 PS, Eastman Kodak Co., Rochester, New York, USA) are representative of the original data. All photographs were taken on Kodak Electronic Imaging Paper (Eastman Kodak Co.).

### Inhibitory assay

Inhibition of C1845 induced cell injury by LB-SCS was determined by infecting the Caco-2/TC7 cells with the C1845 bacteria (10⁴ cfu/ml) at 37°C in 10% CO₂/90% air for three hours with or without LB-SCS. As a control, we used the cell permeable Ca²⁺ chelator BAPTA/AM which prevents C1845 induced F-actin cytoskeleton rearrangements.22 BAPTA/AM in methanol-dimethylformamide (50–50 v/v) was added to the culture medium 60 minutes before infection. The calcium chelator was maintained during the infection time course (three hours). The concentration used did not affect cell integrity, as measured by LDH release (control cells: 36 (5) U/l; H₂O lysed cells: 2995 (25) U/l; BAPTA/AM treated cells: 39 (6) U/l). Moreover, there was no change in C1845 binding (C1845 infected cells: 7.26 (0.14) log cfu/ml; C1845 infected BAPTA/AM treated cells: 7.29 (0.28) log cfu/ml) nor was expression of the apical F-actin network affected (control uninfected cells: 2.80 (0.18) immunofluorescence intensity arbitrary units; uninfected BAPTA/AM treated cells: 2.90 (0.25) arbitrary units).

### Data analysis

Results are expressed as mean (SEM). For statistical comparisons, the Student’s t test was performed.

### RESULTS

#### Antibacterial activity against the Afa/Dr DAEC strain C1845

To determine whether the *L. acidophilus* strain LB isolated from the human gut microflora exerted activity against a diarrhoeagenic pathogen, we focused our study on the SCS in which antibacterial compounds are present.21,22 The antibacterial activity of LB-SCS against the viability of Afa/Dr DAEC strain C1845 was examined in vitro after direct contact between the C1845 bacteria and LB-SCS. Examined as a function of LB-SCS concentration after three hours of contact, dose dependent antibacterial activity was observed (table 1). Highly significant activity was observed at a 2.0-fold concentration of LB-SCS which induced a decrease of 3 logs in C1845 viability whereas MRS was almost inactive at this concentration. A highly significant 5 logs decrease in C1845 viability was observed with a 2.5-fold concentration of LB-SCS whereas only a 2 logs decrease was found for the same MRS concentration.

#### Killing of C1845 bacteria adherent on human enterocyte-like Caco-2/TC7 cells

Adhering C1845 bacteria were observed in confluent differentiated Caco-2/TC7 cells infected apically (10⁴ cfu/ml, three hours at 37°C). As can be seen in fig 1A and 1B, low and high magnifications of a thin section of the C1845 infected Caco-2/

†Antimicrobial activity of LB-SCS in vitro. Colony count assay was performed after incubating 1 ml of phosphate buffered saline containing C1845 bacteria (10⁴ cfu/ml) with 1 ml of MRS or LB-SCS at 37°C for three hours.

‡Antimicrobial activity of LB-SCS in C1845 preinfected Caco-2/TC7 cells. After infection of Caco-2/TC7 cells (10⁸ cfu/ml) with C1845 bacteria for three hours, cells were subjected to MRS, LB-SCS, or gentamicin treatment for one hour at 37°C. Results are presented as mean (SEM) obtained from 3–4 experiments, each in triplicate.

Statistical analysis was performed using a Student’s t test: **p<0.01 compared with control uninfected cells.

LB-SCS, spent culture supernatant of *Lactobacillus acidophilus* LB culture; MRS broth, De Man, Rogosa, Sharpe broth; ND, not determined.
TC7 monolayer showed that the C1845 bacteria infected diffusely the brush border of the fully differentiated Caco-2/TC7 cells. Examined at the level of the brush border, a high magnification transmission electron micrograph showed that the infecting C1845 bacteria were strongly engulfed within elongated MV (fig 1C) and a bacteria associated with multiple elongated microvilli (D) (magnification ×4000 and ×8000, respectively).

The fact that adhering C1845 bacteria were in a close association with MV that engulf the bacteria could hinder their access by antibacterial treatment. The effect of LBS-SCS treatment against adhering C1845 bacteria onto Caco-2/TC7 cells was examined (table 1). A preliminary experiment examined whether or not LB-SCS treatment modified the cell and monolayer integrity of C1845 infected cells. For this purpose, cell viability was measured by determination of release of the intracellular enzyme LDH in the culture medium. No release was observed in LB-SCS treated infected cells compared with untreated cells (control C1845 infected cells: 36 (5) U/l; LB-SCS treated C1845 infected cells: 37 (4) U/l; H2O2 lysed cells: 4272 (61) U/l). A highly significant 3 logs decrease in viable adhering C1845 was observed in preinfected Caco-2/TC7 cells after one hour of treatment with a twofold concentrate of LB-SCS (table 1). For this purpose, cells were infected as reported above (10^6 cfu/ml, three hours at 37°C) followed by extensive washing with PBS to eliminate non-adhering bacteria. Then, C1845 infected cells were subjected for one hour to DMEM with or without LB-SCS (twofold concentrate). As shown in fig 2, a highly significant 3 logs decrease in viable adhering C1845 was observed in preinfected Caco-2/TC7 cells after one hour of treatment with LB-SCS. In C1845 infected cells treated with LB-SCS for one hour and then subcultured in the presence of DMEM, the level of viable adhering bacteria was determined at one, two, and three hours post-treatment. The level of remaining viable adhering bacteria after one hour of treatment remained stable over three hours post-treatment.

**Protection of the F-actin cytoskeleton in enterocyte-like Caco-2/TC7 cells infected by the Afa/Dr DAEC strain C1845**

We have previously reported that Afa/Dr DAEC C1845 infection in Caco-2 cells is followed by a dramatic alteration in the distribution of the major apical cytoskeleton associated proteins that play a pivotal role in MV architecture. We first examined whether the C1845 induced cytoskeleton injury develops as a function of the level of adhering bacteria (fig 3). For this purpose, cells were infected for three hours at 37°C with increasing concentrations of C1845 bacteria. The infected cells were processed for determination of viable adhering bacteria and for direct immunofluorescence labeling of F-actin using the fluorescein labelled phalloidin assay.

Quantification of apical F-actin expression was conducted by measuring relative F-actin immunofluorescence intensity by a
corresponds to MV associated F-actin non was characterised by the disappearance of the homogenous appearance of the apical F-actin disassembly. This phenomenon was demonstrated that dose dependent C1845 induced F-actin rearrangement. Infection of cells with C1845 bacteria (10⁸ cfu/ml, three hours at 37°C) was conducted in the presence of LB-SCS (0.5-fold concentrate). At this concentration, LB-SCS had no activity on C1845 bacterial viability (table 1) or adhesion (C1845 infected cells: 7.25 (0.3) log cfu/ml; C1845 infected LB-SCS treated cells: 7.03 (0.4) log cfu/ml). As observed in fig 4E, high magnification of en face micrographs obtained by conventional epifluorescence microscopy showed that in the presence of LB-SCS, no C1845 induced F-actin disassembly was found compared with C1845 infected cells (fig 4B). Indeed, the normal fine flocculated labelling of F-actin centrally in C1845 infected LB-SCS treated cells (fig 4E) resembled the F-actin distribution in control uninfected cells (fig 4A). Activity was quantified by measuring relative F-actin immunofluorescence intensity in control uninfected untreated cells, untreated C1845 infected cells, and LB-SCS treated C1845 infected cells (table 2). A highly significant increase in F-actin immunofluorescence intensity was observed in LB-SCS treated C1845 infected cells compared with untreated C1845 infected cells. No significant difference was found between control uninfected untreated and LB-SCS treated C1845 infected cells.

As shown in fig 4F, BAPTA/AM treatment of C1845 infected cells resulted in blockade of induced apical F-actin disassembly, as previously reported by us. BAPTA/AM activity was quantified by measuring relative F-actin immunofluorescence intensity showed no significant difference compared with C1845 infected LB-SCS treated cells (control uninfected cells: 2.78 (0.18); C1845 infected cells: 0.32 (0.09); C1845 infected BAPTA/AM treated cells: 2.74 (0.15); C1845 infected LB-SCS treated cells: 2.70 (0.20)). It is interesting to note that protection of the F-actin network observed above for LB-SCS treatment (fig 4E) resembled the activity of BAPTA/AM treatment.

Inhibition of C1845 induced alterations in expression of functional brush border associated proteins

We have previously reported that infection of Caco-2/TC7 cells by Afa/Dr DAEC strain C1845 is followed by a dramatic decrease in the apical expression of the differentiation associated brush border associated hydrolases SI and DPP IV, and the fructose transporter GLUT5. The impact of LB-SCS at a concentration which does not affect bacterial viability or adhesion on expression of brush border associated functional proteins in C1845 infected cells was examined. Caco-2/TC7

Caco-2/TC7 cells were infected for three hours at 37°C with C1845 bacteria (10⁸ cfu/ml) with or without LB-SCS (2.0-fold concentrate). RI, relative immunofluorescence intensity expressed as arbitrary units, measured at the apical domain by conventional immunofluorescence microscopy; LB-SCS, spent culture supernatant of Lactobacillus acidophilus LB culture. Results are mean (SEM) obtained from three experiments, each in duplicate. Statistical analysis was performed using a Student’s t test: ** p<0.01 compared with control uninfected cells; †† p<0.01 compared with C1845 infected cells.
cells were apically infected with C1845 alone (10^8 cfu/ml, three hours at 37°C) or in the presence of LB-SCS (0.5-fold concentrate). Indirect immunofluorescence labelling was conducted in unpermeabilised cells thus allowing us to detect the protein present within the brush border. We chose to examine expression of four brush border associated functional proteins, the hydrolases SI and DPP IV, the GPI anchored protein AP, and the fructose transporter GLUT5.

Immunolabeling of SI, DPP IV, and GLUT5 observed by conventional immunofluorescence microscopy in unpermeabilised control uninfected cells revealed the typical mosaic pattern of distribution of MV associated functional proteins. For AP distribution, the fine punctuate labelling was typical of the distribution of brush border GPI anchored proteins. In C1845 infected cells, the apical distribution of SI, DPP IV, GLUT5, and AP was profoundly disorganised compared with control uninfected cells. Central labelling in cells totally disappeared, showing instead lucent zones. The relative immunofluorescence intensities of SI, DPP IV, GLUT5, and AP measured in C1845 infected cells were highly significantly decreased compared with control uninfected cells (table 3). When SI, DPP IV, GLUT5, and AP immunolabelling was examined in C1845 infected LB-SCS treated cells, the apical distribution of this brush border associated protein was found to be maintained. The relative immunofluorescence intensities of SI, DPP IV, GLUT5, and AP measured in C1845 infected LB-SCS treated cells were not significantly different from those measured in control uninfected cells (table 3).

RI, relative immunofluorescence intensity expressed as arbitrary units, measured at the apical domain by conventional immunofluorescence microscopy in unpermeabilised cells. Band, size of the immunofluorescent band (µm) measured by confocal laser scanning microscopy in permeabilised cells (vertical z–x optical section). SI, AP, DPP IV, GLUT5, sucrase-isomaltase, alkaline phosphatase, dipeptidylpeptidase IV, and fructose transporter, respectively; LB-SCS, spent culture supernatant of Lactobacillus acidophilus LB culture. Data are mean (SEM) from three experiments. Statistical analysis was performed using a Student’s t test: *not significant, **p<0.01 compared with control uninfected cells.
The observed disappearance of expression of brush border associated functional proteins from the apical surface of C1845 infected cells described above and the fact that on LB-SCS treatment these functional proteins remained present, prompted us to examine the intracellular distribution of these proteins. For this purpose, CLSM analysis in permeabilised cells was conducted which allowed observation of immunolabelled SI, DPP IV, GLUT5, and AP proteins at successive sections of the polarised cells (table 3). For example, as shown in fig 5, by reconstruction from x–z sections of CLSM, an optical section perpendicular to the plane of monolayer (x–z) shows that expression of DPP IV in control uninfected Caco-2/TC7 cells was strikingly localised at the apical surface of the cell monolayers showing a homogenous and tight band (fig 5D, table 3). This observed distribution is consistent with the known insertion of functional proteins in the brush border membrane of epithelial cells of the small intestine.23 24 In C1845 infected cells, CLSM analysis revealed that proteins remained present but significant enlargement of the bands was observed (fig 5E, table 3). In C1845 infected LB-SCS treated cells, SI, DPP IV, GLUT5, and AP immunolabelling remained tight without large lucent zones (fig 5F, table 3).

DISCUSSION

We examined whether a lactobacillus strain isolated from the human adult microflora protected infected human intestinal cells against brush border lesions induced by a diarrhoeagenic E coli. We found that the spent culture supernatant of Lactobacillus acidophilus LB culture (LB-SCS) which contained antibacterial compounds11 16 efficiently killed the Afa/Dr DAEC C1845 bacteria, both when direct contact between the pathogen and LB-SCS was performed, and when LB-SCS treatment was applied to bacteria that adhered to the human intestinal cells Caco-2/TC7. The antibacterial activity of LB-SCS against strain C1845 resembled that previously observed against S typhimurium infecting cultured human enterocyte-like Caco-2 cells and conventional mice.13 14 We have previously demonstrated that the antibacterial substances secreted by the L acidophilus LB strain were heat stable, of low molecular weight, and distinct from lactic acid.15 Interestingly, we have recently reported that bifidobacteria strains isolated from the human infant microflora also produced low molecular weight antimicrobial substances which were active in vitro against pathogens and in vivo against S typhimurium infecting germ-free mice.16 Some of the antimicrobial molecules produced by species of the gut microflora and involved in the barrier effect remain to be purified and chemically characterised.

We reported here that the human L acidophilus strain LB by its SCS antagonised alterations in expression of brush border associated structural and functional proteins promoted by a diarrhoeagenic E coli in cultured human enterocyte-like cells. In the gut epithelium, polarisation organisation of intestinal cells is essential for achievement of specialised functions, including absorption and secretion.25 Indeed, this polarisation results in the presence of three domains in the plasma membrane: the apical surface facing the lumen, the lateral surface facing adjacent cells, and the basal surface underlying connective tissue. The brush border facing the external compartment is composed of a dense lawn of uniform MV for which the ultrastructure and biochemical composition have been extensively investigated.26 27 The cytoskeleton rearrangements observed on Afa/Dr DAEC infection in intestinal Caco-2/TC7 cells were characterised by a dramatic alteration in F-actin and villin protein distribution,28 29 which play a pivotal role in the establishment and maintenance of MV architecture.30 Potential implications in functional disorders resulting from alterations in the cytoskeleton of polarised epithelial cells have been

Figure 5  Effect of spent culture supernatant of Lactobacillus acidophilus LB culture (LB-SCS) treatment at concentrations which did not affect Afa/Dr DAEC C1845 viability or adhesion, on induced dipeptidylpeptidase IV (DPP IV) rearrangements analysed by confocal laser scanning microscopy (CLSM) in human enterocyte-like Caco-2/TC7 cells. Experimental conditions were as in fig 3. Cells were fixed with 3.5% paraformaldehyde, washed, and processed for indirect immunofluorescence labelling of DPP IV (tetramethyl rhodamine isothiocyanate labelling), as described in materials and methods. The samples were analysed by serial optical horizontal sectioning using a Zeiss confocal laser scanning microscope. Section starts at the apical domain of the cells and the following analysis was conducted until the basal domain. (A, D) Control uninfected cells. (B, E) C1845 infected cells. (C, F) C1845 infected cells treated with LB-SCS (0.5-fold concentrate). (A, B, C) Light microscopy micrographs of semithin sections perpendicular to the bottom of the flask (magnification ×40). (D, E, F) En face micrographs of the lateral views of the immunolocalisation of DPP IV obtained by CLSM analysis (vertical x–z optical section). In control cells, DPP IV labelling was localised at the apical domain in a homogenous band (D). In C1845 infected cells, apical DPP IV labelling was dramatically modified showing disruption in apical labelling and rearrangement of the protein in a non-homogenous band (E). In C1845 infected cells treated with LB-SCS (0.5-fold concentrate), DPP IV labelling remained localised at the apical domain in a homogenous band (F), as observed in control uninfected cells, and adhering bacteria appeared at the apical domain of the cells (C). Micrographs are representative of two experiments conducted in duplicate. Similar results were obtained for GLUT5 and AP (not shown).
demonstrated in a variety of disease processes. Altered calcium homeostasis in metalloproteins, as well as various other molecules, plays a pivotal role in cell architecture, thus affecting the viability or adhesive capacity of the pathogen. To accomplish an adaptive reorientation of the brush border, cell signaling leading to functional disorders promoting diarrheic diseases. The present report provides new insight into the ciliated mechanisms of pathogenicity.
