Upper gastrointestinal bleeding and surrogate end points

In their paper, Hawkey et al (Gut 2001;49:372–9) report on the use of blood in the stomach as a surrogate of hard end points such as rebleeding, need for surgery, and death in a group of patients with upper gastrointestinal bleeding randomised to placebo, tranexamic acid, lansoprazole, or both lansoprazole and tranexamic acid. Using logistic regression analyses, they found that blood in the stomach was predictive of clinical outcome and that the active medications decreased the gastric pool size at endoscopy. The authors suggest that although the medications did not significantly improve the rates of clinical outcomes, they would probably do so in a trial of sufficient sample size given the effect achieved on the surrogate endoscopic end point. These conclusions should be viewed with caution, if not with skepticism, for several reasons. Firstly, it is interesting that the authors chose the presence of blood in the stomach as a substitute end point based on a previous study in which no statistical difference was found for the prevalence of this endoscopic sign alone between patients ran- 

cence was found for the prevalence of this previous study in which no statistical differ-

Author’s reply

The choice of the amount of blood in the stomach was made prospectively in the design of this trial so the results are more than exploratory. However, we agree that the possibility that blood in the stomach is predictive of drug effects needs to be verified prospectively. The purpose of our study was to try to identify a relatively quick screening method that did not involve several thousand patients. Our study was started before the BSG guidelines on high and low risk patients and was made on individual clinical judgement. However, as noted in the paper, doctors in our hospital receive a card indicating high risk factors (tachycardia, hypotension, gastric ulceration, oesophageal varices, and comorbidity) guiding them about risk factors. Finally, we agree that several thousand patients would be needed to show a clinical end point. We conducted our study with a view to a two stage approach to drug treatment—show an effect on the surrogate end point before designing the large trial to help to focus a choice of agents for research.

Gluten exposure and risk of autoimmune disorders

We applaud the paper from Sategna Guidetti et al (Gut 2001;49:302–5) showing that, contrary to what was described in a paediatric population, there is no clear relationship between gluten exposure and risk of autoimmune disease (AID) in adult patients affected by coeliac disease (CD). Although in our clinical experience we have seen CD patients developing AID after many years on a strict gluten free diet, we thought that the data published by Ventura and colleagues should have been easily confirmed

References

in an adult population. However, in common with Sategna Guidetti et al, this did not appear to be the case in the coeliac patients under our care. Moreover, although Sategna Guidetti et al could at least confirm the relationship between age at diagnosis of CD and risk of developing AID found by Ventura et al, we could not confirm this finding.

We retrospectively studied the notes of 462 adult patients affected by CD attending our outpatient clinic. All had been diagnosed on the basis of villous atrophy in jejunum biopsy specimens which improved after withdrawal of dietary gluten. There were 327 females and mean age at diagnosis of CD was 33.3 ± 15.6 years (range 1–79). Ninety six patients were affected by at least one AID. Age at diagnosis of CD did not differ between CD patients with and without AID (32.6 ± 35.5 years; p=0.6). The prevalence of AID was not related to age at diagnosis of CD (x2, p=0.7). However, an upward trend, similar to that shown by Ventura et al, was noted in the first three decades (Fig 1).

Since we had previously shown that diagnostic delay is a very important feature in the history of CD, we hypothesised that the longer the diagnostic delay the greater was the risk of developing AID. However, the prevalence of AID was not related to duration of diagnostic delay. Moreover, remarkably, diagnostic delay in patients with CD and AID was significantly shorter than that of patients with CD but not AID (9.1 ± 13.2 years; p=0.02). We feel that this is a sensible result. The more reasons a patient has to be diagnosed, the more likely it is that he/she will be diagnosed sooner. However, this strongly argues against a relationship between the risk of AID and exposure to gluten.

Finally, as we agree with Sategna-Guidetti et al on the fact that dermatitis herpetiformis should not have been considered, we analysed our data both including and excluding this skin condition. The final outcome was unaffected.

In conclusion, our data in adult patients with CD confirm those of Sategna-Guidetti et al. Our only finding that was similar to that of Ventura et al was an upward trend in the first three decades. As patients affected by latent CD clearly prove that CD can start in adult life and not exclusively during childhood, this upward trend could mean that the findings of Ventura et al are valid only for the paediatric age. However, as Londei points out, the only way to answer this question would involve an unacceptable prospective study.

Active or inactive end metabolites which have both toxic and non-toxic properties. Secondly, thiopurine users can be broadly divided into clinically overlapping responders, non-responders, and therapy intolerant groups which in turn correspond to concentrations of these end metabolites. Exclusion of any of these end metabolite dependent patient sub-populations can significantly influence study outcome.

Failure to find a significant association between thiopurine related toxicity or disease activity and 6-TGN concentrations by Lowry et al could be explained by the median whole blood 6-TGN concentration (136 pmol/8x10⁹ red blood cells (RBC)) in the study population. This is well below the pharmacologically suggested therapeutic concentration of 230 pmol/8x10⁹ RBC. In a separate study, Dubinsky and colleagues were able to show that significantly high isolated 6-TGN concentrations were not related to toxicity. They in fact demonstrated a clinical improvement with increasing 6-TGN concentrations while toxicity was directly proportional to increasing 6-mercaptopurine, a thiopurine compound not subject to the 6-MMPR catabolic pathway, may offer a more realistic approach to study the correlation between 6-TGN concentrations and disease activity in IBD patients.

Author’s reply
There are numerous factual inaccuracies in Qasim et al’s letter which merit response. Firstly, they state that “A number of competitive enzymes, including thiopurine methyltransferase (TPMT), are involved in the complex multistep thiopurine metabolism and result in the synthesis of varying concentrations of active or inactive end metabolites which have both toxic and non-toxic properties”. They reference a nine year old review article for this statement. While there is no argument that the metabolism of azathioprine and 6-mercaptopurine is complex, and that it involves multiple enzymes, there is very
little valid information about which metabolites are toxic or non-toxic. The clear bias of Qasim et al. is that various metabolites are either active or inactive and that some have toxic properties while others are non-toxic, but this has not been definitively proved in statistically valid clinical studies.

Secondly, Qasim et al. state that “thiopurine users can be broadly divided into clinically overlapping responders, non-responders, and therapy intolerant groups”, which in turn correspond to concentrations of these end metabolites. Exclusion of any of these end metabolite dependent patient subpopulations can significantly influence study outcome. The two papers quoted have exactly the same methodology are unlikely to account for the discrepant results. Thirdly, Qasim et al. state that the lack of an association between thiopurine toxicity or disease activity and 6-thioguanine nucleotide (6-TGN) concentrations in our study could be explained by the variability of blood 6-TGN concentrations. The authors should refer to paragraph 4 of the discussion on page 699 of our paper that indicates that our group has performed a study that shows a strong direct correlation between the assay used by Cuffari and Dubinsky and the assay used in our study (unpublished data). A conversion factor of 1.6 is required to convert the results of our study to those of the Cuffari and Dubinsky studies. We disagree strongly with this statement. The study by Dubinsky et al. was an uncontrolled open label pilot study in 10 patients with Crohn’s disease. It is unreasonable to compare the results of our study (a study involving 170 patients) with the preliminary results from an open label pilot study in 10 patients.

We agree with Qasim et al. on one point—that is, that a prospective trial is needed in which patients who are candidates for thiopurine therapy are randomly assigned to full dose azathioprine (2–3 mg/kg/day) or 6-mercaptopurine (1–2 mg/kg/day) with downward adjustments in dose, as clinically indicated for toxicity, versus dose adjustment to a target 6-TGN concentration range. The issue of patient subpopulations based on metabolite profiles is very preliminary (one published study in 10 patients) and this hypothesis needs further characterisation before a controlled trial can even be designed. In the meantime, routine measurement of RBC 6-TGN in patients being treated with azathioprine or 6-mercaptopurine is not necessary.

Serum leptin and body mass index in children with H pylori infection
Leptin, a protein product of the obese gene expressed primarily by adipocytes, is known to regulate food intake, energy expenditure, and body weight homeostasis. Leptin has recently been detected in rat gastric mucosa, and elevated leptin levels have been found in the gastric mucosa of patients with Helicobacter pylori associated gastritis. In a study on the effect of H pylori infection on gastric leptin expression, Azuma et al (Gut 2001; 49:324–9) demonstrated that gastric leptin may play a role in weight gain after eradication of H pylori infection. We read their article with great interest and would like to add a comment concerning serum leptin and body mass index (BMI). The authors showed a significant increase in gastric leptin expression in patients with H pylori infection, and a significant reduction in gastric leptin expression with a concomitant increase in BMI after successful eradication therapy. On the other hand, the immuno-pathogenesis of H pylori associated gastritis in children is considered to be different from that in adults. This may account for the difference in gastric leptin expression between adults and children.
