Incidence of gastroduodenal ulcers in patients with rheumatoid arthritis after 12 weeks of rofecoxib, naproxen, or placebo: a multicentre, randomised, double blind study

C J Hawkey, L Laine, T Simon, H Quan, S Shingo, J Evans, on behalf of the Rofecoxib Rheumatoid Arthritis Endoscopy Study Group

Background: Previous studies in patients with osteoarthritis have suggested that the selective cyclooxygenase (COX)-2 inhibitor rofecoxib results in less gastrointestinal damage than non-selective non-steroidal anti-inflammatory drugs (NSAIDs). This study compared the incidence of endoscopically detected gastroduodenal ulcers in rheumatoid arthritis patients treated with rofecoxib or a non-selective NSAID.

Methods: In this multicentre, randomised, double blind, 12 week study, patients with rheumatoid arthritis were allocated to rofecoxib 50 mg once daily (n=219), naproxen 500 mg twice daily (n=220), or placebo (n=221). Endoscopy was performed at baseline and at six and 12 weeks. Life-table analysis and log rank tests were used to analyse the incidence of gastroduodenal ulcers ≥3 mm. Gastric or duodenal ulcers ≥5 mm and erosions were also evaluated as secondary end points. Tolerability was assessed by adverse events.

Results: The cumulative incidence of ulcers ≥3 mm at 12 weeks was significantly higher in patients on naproxen (25.5%) than in patients receiving rofecoxib (6.8%; difference 18.7%; 95% confidence interval [CI] 11.7%, 25.7%; p<0.001) or placebo (2.9%; difference 22.6%; 95% CI 16.1%, 29.1%; p<0.001). The difference between rofecoxib (6.8%) and placebo (2.9%) did not reach statistical significance (p=0.066). Results were similar for ulcers ≥5 mm and for mean changes from baseline in the number of gastroduodenal erosions. The overall incidence of clinical adverse events was similar among treatment groups (61% of patients on placebo, 62% in patients on rofecoxib, and 66% in patients on naproxen).

Conclusions: Rofecoxib 50 mg daily (twice the dose recommended for this patient population) resulted in a lower incidence of endoscopically detected gastroduodenal ulcers and erosions than treatment with naproxen 500 mg twice daily.

The potential of non-steroidal anti-inflammatory drugs (NSAIDs) to cause gastrointestinal toxicity is well known, with an estimated 100 000 hospitalisations occurring annually in the USA due to NSAID related serious gastrointestinal complications.1 Chronic use of NSAIDs puts patients at risk for perforations, ulcers, or haemorrhage of the gastroduodenal mucosa.2 It has been postulated that these deleterious effects are a result of inhibition of cyclooxygenase (COX)-1, the isoform of the enzyme cyclooxygenase believed to catalyse the synthesis of gastroprotective prostaglandins.1 By contrast, NSAIDs are thought to achieve their anti-inflammatory or analgesic efficacy by inhibition of COX-2, the isoform involved in inflammatory responses.3 The lack of selectivity of traditional NSAIDs for a particular COX isoform is a likely explanation for the apparent inseparability of the toxic effect of COX-1 inhibition and the therapeutic effect of COX-2 inhibition seen with these agents. This has led to the development of COX-2 selective inhibitors, based on the premise that preferential inhibition of the isoform relevant to inflammation (COX-2) would be expected to convey the same therapeutic benefit of traditional NSAIDs with significantly less gastrointestinal toxicity due to inhibition of COX-1.1 4

Current knowledge of the COX-2 inhibitor rofecoxib has been consistent with the COX-2 hypothesis, in that rofecoxib is not only as effective as non-selective NSAIDs but is also well tolerated both in general and in terms of the gastrointestinal system.4 6 Specifically, while naproxen 500 mg twice daily caused a 70% reduction in gastric mucosal prostaglandin synthesis, rofecoxib 25 mg and 50 mg had no such effect.4 Similarly, faecal blood loss and intestinal permeability, both thought to be useful markers of the potential of an NSAID to cause clinically significant gastrointestinal toxicity,4 6 were increased in healthy subjects who received indomethacin 150 mg or ibuprofen 250 mg, but not in subjects receiving rofecoxib 25 mg or 50 mg.4 6

Endoscopic evaluation of the effect of rofecoxib on the gastrointestinal mucosa has further demonstrated its favourable gastrointestinal safety profile in comparison with non-selective NSAIDs. In healthy subjects treated for seven days, ibuprofen 2400 mg and aspirin 2600 mg were each associated with an increased incidence of erosions in healthy subjects in comparison with placebo, whereas rofecoxib 250 mg (a supratherapeutic dose) given daily for seven days was not.4 6 Consistent with these results, two endoscopy studies in more than 1500 osteoarthritics (OA) patients over the age of 50 years showed that the incidence of ulcers over three months in patients receiving daily rofecoxib 25 mg or 50 mg was similar to that in patients on placebo and less than that in patients on...
ibuprofen 2400 mg. Moreover, the clinical relevance of these endoscopic findings was demonstrated by an analysis of the results of eight phase II/III studies involving over 5400 OA patients. In this analysis, rofecoxib resulted in a significantly lower incidence of gastrointestinal perforations, ulcers, and bleeding episodes (PUBs) compared with non-selective NSAIDs.

In addition to their role in the treatment of OA and pain, NSAIDs are also an important component of treatment for rheumatoid arthritis (RA). Because high and/or chronic dosing with NSAIDs, as well as concomitant use of corticosteroids, may put RA patients at greater risk for upper gastrointestinal ulcers compared with placebo, the safety of rofecoxib in RA patients (the VIGOR trial) showed that rofecoxib 50 mg daily was associated with significantly fewer upper gastrointestinal events (symptomatic ulcers, perforations, bleeds, and obstructions) than naproxen 500 mg twice daily, results similar to those observed in OA patients. An endoscopy study was conducted to examine further the gastrointestinal safety profile of rofecoxib compared with that of NSAIDs in RA patients.

**METHODS**

**Study population**

All patients participating in the study gave written informed consent and the study was conducted in conformance with applicable country or local ethics requirements. The study was conducted at 48 sites in 18 countries. Patients between the ages of 21 and 85 years were enrolled, with a confirmed clinical diagnosis of RA and a requirement of at least three months of NSAID therapy. Patients were excluded if they had an oesophageal, gastric, or duodenal ulcer, pyloric obstruction, or erosive oesophagitis at baseline endoscopy. Patients were also excluded if they had any of the following: creatinine level >2.0 mg/dl; creatinine clearance ≤30 ml/min; bleeding diathesis; requirement for anticoagulants, low dose aspirin, ticlopidine, or clopidogrel; unstable medical disease including current angina or congestive heart failure; previous upper gastrointestinal surgery; faecal occult blood; history of inflammatory bowel disease, history of myocardial infarction, coronary angioplasty, or coronary artery bypass graft within one year, cerebrovascular event or active hepatic disease within the past two years, or malignancy within the past five years. The study population included patients infected with *Helicobacter pylori*, a prior history of a gastroduodenal PUB, or the presence of gastroduodenal erosions at baseline endoscopy.

**Design**

This was a randomised, double blind, placebo controlled, parallel group study.

**Procedures**

Following a two week washout period from non-selective NSAIDs and any antisecretory or cytoprotective drugs, patients who met entry criteria underwent baseline upper gastrointestinal endoscopy and determination of *H pylori* status by gastric biopsy with a rapid urease test (CLOtest) and by histology. Patients were then randomised to one of three treatment groups: rofecoxib 50 mg once daily, naproxen 500 mg twice daily, or placebo, for 12 weeks. Matching placebo for each medication was used to maintain blinding. Treatment allocation was stratified by history of significant upper gastrointestinal disease (gastroduodenal ulcer or upper gastrointestinal haemorrhage or perforation), and each stratum was further stratified according to concomitant use of oral corticosteroids during the study. Stable doses of non-study antithrombotic medications other than NSAIDs and antisecretory or cytoprotective drugs were permitted, as were injectable or oral corticosteroids (≤10 mg prednisone or equivalent daily). Rescue medications (acetaminophen/paracetamol for pain and Gelusil aluminum hydroxide/magnesium hydroxide/simethicone (WARNER-Lambert) for minor dyspepsia) were provided. Patients were prohibited from using the following medications throughout the study: H₂ receptor antagonists, proton pump inhibitors, prostaglandin analogues, other gastroprotective agents, calcium containing antacids, anti-coagulants, antiplatelet therapy, and cyclosporin.

Patients were evaluated clinically at study weeks 3, 6, 9, and 12. Endoscopy was performed at baseline, at study weeks six and 12, at unscheduled discontinuation, and when deemed clinically necessary by the investigator. At endoscopy, the number and size of gastric and/or duodenal ulcers (defined as mucosal breaks with an unequivocal depth of at least 3 mm in the longest dimension) were recorded, and gastroduodenal mucosal erosions were counted. If an ulcer was detected, the patient was immediately discontinued from the study and underwent discontinuation procedures and ulcer treatment. Safety assessments also included physical examination and vital signs, laboratory parameters, and monitoring of clinical and laboratory adverse events throughout the study.

**Statistical analysis**

The cumulative incidence of gastric and/or duodenal ulcers ≥3 mm over 12 weeks was the primary end point of the study. A survival analysis was used to analyse time to event data for ulcer incidence, and the log rank test was used to compare the cumulative incidence of ulcers among treatment groups. Twelve week cumulative rates were estimated via Kaplan-Meier, and the Breslow-Crowley method was used to calculate 95% confidence intervals (CIs); 95% CIs were also calculated for between treatment differences and the ratio of the 12 week cumulative rates for the prespecified comparisons. Although the study was not designed to compare rofecoxib with placebo, p values were calculated for comparisons with placebo.

Twelve week cumulative ulcer incidence rates of 7.5% for rofecoxib, 7.5% for placebo, and 25% for naproxen were assumed. The study had 98% power to detect such differences between rofecoxib or placebo versus naproxen, based on a two sided test with α=0.05.

Assessment of treatment effect on ulcer incidence was made for patient subgroups to explore the consistency of effects across subgroups. These classifications were defined at baseline by the following: age (<65 or >65 years), sex, race (White or non-White), history of symptomatic PUB, H pylori status, baseline number of gastric and/or duodenal erosions (0 or ≥0), prior NSAID use, tobacco use, corticosteroid use, and geographical region (USA or international). A Cox proportional hazards model was used to test qualitative treatment by subgroup interactions.

Cumulative incidence of ulcers ≥5 mm over 12 weeks, and mean change from baseline number of erosions over 12 weeks were assessed as secondary end points. Continuous variables were analysed with an analysis of covariance model (with prespecified factors of treatment, gastrointestinal history, corticosteroid use, and baseline covariate where appropriate). Adverse event data were analysed by Fisher’s exact test.

**RESULTS**

**Patient characteristics**

Figure 1 shows the disposition of patients throughout the study. Of the 660 patients enrolled at the randomisation visit, 509 completed the study. Nine, 11, and 22 patients discontinued due to adverse experiences on placebo, rofecoxib, and naproxen, respectively, while 11, four, and two patients, respectively, discontinued due to lack of efficacy. As shown in table 1, there were no clinically meaningful differences among groups with regard to age, sex, race, history of gastrointestinal...
The six and 12 week incidences of ulcers and erosions, or prior NSAID use.

Incidence of ulcers

A similar pattern of treatment effects was seen when gastric and duodenal ulcers were examined separately. The cumulative incidence of gastric ulcers ≥3 mm at 12 weeks was 2.0% for placebo, 5.9% for rofecoxib, and 22.1% for naproxen. The respective (difference for naproxen vs rofecoxib (95% CI) 11.8% (5.7%, 18.0%); p<0.001; difference for naproxen vs placebo 14.2%, p<0.001). The incidence in the rofecoxib group did not differ significantly from that in the placebo group (2.9%; p=0.210). As shown in fig 4, the least squares mean change from baseline in the number of erosions was significantly higher in patients on naproxen compared to those on rofecoxib (difference (95% CI) 4.05 (93.37, 4.73); p<0.001) and in patients on naproxen vs placebo (difference (95% CI) 4.41 (3.73, 5.08); p<0.001). There was no significant difference between patients on placebo and patients on rofecoxib.

NSAIDs, non-steroidal antiinflammatory drugs; GI, gastrointestinal; PUBs, gastrointestinal perforations, ulcers, or bleeding episodes.

Incidence of ulcers and erosions

The six and 12 week incidences of ulcers ≥3 mm are shown in fig 2. The 12 week cumulative incidence of gastroduodenal ulcers ≥3 mm in patients on naproxen 500 mg twice daily (25.5%) was significantly greater than that in patients on rofecoxib 50 mg (6.8%; between treatment difference 18.7% (95% CI 11.7%, 25.7%; p<0.001) or placebo (2.9%; difference 22.6% (95% CI 16.1%, 29.1%; p<0.001) whereas the incidence in patients on rofecoxib did not differ significantly from that in patients on placebo (2.9%; p=0.066). Findings for ulcers ≥5 mm were similar and are shown in fig 3. The 12 week cumulative incidence of ulcer ≥5 mm was 2.9%, 5.3%, and 17.1% in patients on placebo, rofecoxib, and naproxen, respectively (difference for naproxen vs rofecoxib (95% CI) 11.8% (5.7%, 18.0%); p<0.001; difference for naproxen vs placebo 14.2%, p<0.001). The incidence in the rofecoxib group did not differ significantly from that in the placebo group (2.9%; p=0.210). As shown in fig 4, the least squares mean change from baseline in the number of erosions was significantly higher in patients on naproxen versus those on rofecoxib (difference (95% CI) 4.05 (93.37, 4.73); p<0.001) and in patients on naproxen versus patients on placebo (difference (95% CI) 4.41 (3.73, 5.08); p<0.001). There was no significant difference between patients on placebo and patients on rofecoxib.

A similar pattern of treatment effects was seen when gastric and duodenal ulcers were examined separately. The cumulative incidence of gastric ulcers ≥3 mm at 12 weeks was 2.0% for placebo, 5.9% for rofecoxib, and 22.1% for naproxen. The...
In the present study, rofecoxib 50 mg (twice the recommended dose for the treatment of RA) resulted in significantly fewer endoscopically detected gastroduodenal ulcers \( \geq 3 \text{ mm} \) at 12 weeks compared with naproxen 500 mg twice daily. This was also true for ulcers \( \geq 3 \text{ mm} \) at 12 weeks was 2.3% for placebo, 8.3% for rofecoxib, and 17.9% for naproxen.

**Tolerability**

Table 2 summarises the tolerability assessments. There was no significant difference among treatment groups in the overall incidence of adverse events, although the incidence of drug related adverse events was higher in patients on naproxen and those on rofecoxib compared with those on placebo \((p=0.002)\) for naproxen \(v\) placebo; \(p=0.030\) for rofecoxib \(v\) placebo). Patients taking naproxen had a significantly higher rate of discontinuations due to an adverse event compared with the placebo group \((p=0.036)\).

Comparison of the incidence of serious clinical adverse experiences among treatment groups showed no significant differences \((2.7\% \text{ for placebo, } 1.8\% \text{ for rofecoxib, and } 4.1\% \text{ for naproxen})\) (table 2). One death was reported among patients taking naproxen \((\text{hepatic and multiple organ failure})\) in a patient discovered to be seropositive for hepatitis B. This was considered definitely not related to the study drug by the investigator.

The three adverse events most commonly reported over the entire study were epigastric discomfort, dyspepsia, and heartburn, each of which was reported in at least 5% of patients in each treatment group. No significant difference was observed among treatment groups for the incidence of dyspepsia \((6.3\% \text{ on placebo, } 10.0\% \text{ on rofecoxib, and } 7.3\% \text{ on naproxen})\) or heartburn \((5.0\% \text{ on placebo, } 9.1\% \text{ on rofecoxib, and } 7.3\% \text{ on naproxen})\); however, the rofecoxib group \((9.1\%)\) and the placebo group \((8.6\%)\) both had significantly lower incidences of epigastric discomfort compared with the naproxen group \((17.3\% \text{ for placebo, } 9.1\% \text{ on rofecoxib, and } 7.3\% \text{ on naproxen})\).

The percentages of patients who discontinued because of an adverse event involving the digestive system or abdominal pain were 0.9% on placebo, 3.7% on rofecoxib, and 6.8% on naproxen. The difference between the naproxen and placebo groups was statistically significant \((5.9\% \text{ for placebo, } p=0.001)\) but the difference between the rofecoxib and placebo groups was not \((p=0.062)\). There were seven PUBs \((\text{one patient on placebo, two patients on rofecoxib, and four patients on naproxen})\).

Because COX inhibition has known renal and vascular effects, analyses were prespecified for comparisons between groups for adverse experiences involving hypertension, oedema, or congestive heart failure (table 3). The reported incidences of hypertension were 2.3% for the placebo group, 6.4% for the rofecoxib group, and 0.9% for the naproxen group, and lower extremity oedema was reported for 1.8% of patients on placebo, 1.4% of patients on rofecoxib, and 0% of patients on naproxen. No patient discontinued treatment with the study drug due to either hypertension or lower extremity oedema. Likewise, there were no between treatment group differences observed for the incidences of congestive heart failure adverse events, which were reported for one patient in the study \((\text{rofecoxib group})\). This patient’s event was considered not serious and not related to study drug by the investigator.

**Discussion**

In the present study, rofecoxib 50 mg \((\text{twice the recommended dose for the treatment of RA})\) resulted in significantly fewer endoscopically detected gastroduodenal ulcers \( \geq 3 \text{ mm} \) at 12 weeks compared with naproxen 500 mg twice daily. This was also true for ulcers \( \geq 3 \text{ mm} \), which some clinical experts have
argued may be more clinically meaningful than those ≥3 mm.57 The latter findings are particularly compelling in view of the fact that ulcers ≥3 mm but <5 mm resulted in immediate patient discontinuation, a stipulation which may have interrupted the development of some larger ulcers (≥5 mm) and led to a conservative comparison with rofecoxib. Despite this, a significant advantage with rofecoxib 50 mg persisted compared with naproxen 500 mg twice daily. Rofecoxib 50 mg also demonstrated significantly lower increases in the number of gastroduodenal erosions at 12 weeks compared with naproxen 500 mg twice daily.

A prior history of PUBs was observed to be a positive risk factor for ulcer, as reported previously.16–31 Patients with a prior history of PUBs are known to have an increased risk of ulceration when taking NSAIDs.26–28 Age ≥65 years and White race (v non-white) were also identified as risk factors for the development of gastroduodenal ulceration in this study. While older age has been previously identified as a potential risk factor for the development of endoscopic ulcers in patients with RA, race has not been previously identified as a factor in other studies. The clinical significance of this finding is unclear. However, the advantage of rofecoxib 50 mg over naproxen 500 mg twice daily was maintained in all these subgroups. H pylori status was not a risk factor for the development of ulcers in this study.

There were no statistically significant differences in the incidence of ulcers or erosions for the comparison of rofecoxib with placebo whereas naproxen showed a significant increase relative to placebo on all measures. There was a numerical increase in ulcers and erosions for rofecoxib relative to placebo, raising the possibility that this dose of rofecoxib may slightly increase ulcer rates in RA patients, unlike findings previously reported in OA. A previous combined analysis of OA endoscopy studies established statistical equivalence to placebo for a daily dose of 25 mg, but not for 50 mg.23 This suggests that the numerical increase versus placebo seen in this study may have been less pronounced (or non-existent) at a lower dose.

Interestingly, the ulcer incidence rate in patients on placebo (2.9%) was lower than the incidence rates previously observed in two studies of similar design which assessed the incidence of gastroduodenal ulceration over 12 weeks in patients with OA.16–31 These previous studies showed placebo ulcer incidences over 12 weeks of 9.92% and 3.10%, respectively. The significant variability in the incidence of endoscopic ulcers in patients taking placebo in these individual trials is consistent with the conclusion that small between treatment group differences in rates of endoscopic ulcer may not reflect clinically significant differences in drug effect. By contrast, the highly statistically significant differences from the naproxen 500 mg twice daily group in ulcer incidence in both the placebo and rofecoxib 50 mg groups are consistent with the results of a large clinical outcomes trial in RA patients that demonstrated a significant decrease in the incidence of clinical events of PUBs with rofecoxib 50 mg (a higher dose than recommended) compared with naproxen 500 mg twice daily (a standard dose).30 This large study also compared a standard dose of naproxen with a dose of rofecoxib that is higher than recommended.

Rofecoxib 50 mg demonstrated a favourable safety profile compared with naproxen 500 mg twice daily and was well tolerated over the 12 week treatment period. The overall incidence of clinical and laboratory or serious adverse experiences was generally similar between the rofecoxib 50 mg, naproxen 500 mg twice daily, and placebo groups. Naproxen had the highest rate of drug related adverse experiences and placebo had the lowest rate. The rate of discontinuation due to adverse experiences was significantly greater in patients on rofecoxib 50 mg and placebo groups whereas the incidence of discontinuation due to adverse experiences was significantly greater in patients on naproxen 500 mg twice daily compared with those on placebo.

The adverse event profile was also supportive of better gastrointestinal tolerability for rofecoxib 50 mg than for naproxen 500 mg twice daily. Naproxen resulted in a significantly increased incidence of discontinuations due to adverse experiences of the digestive system or of abdominal pain whereas the incidence of these adverse experiences in patients on rofecoxib was less than that in patients on naproxen and not significantly different from placebo. Due to the small sample size and low incidence of upper gastrointestinal PUBs in this study, a significant difference in the incidence between treatment groups was not expected and therefore these data were not analysed. Data have previously

been published showing that upper gastrointestinal PUBs are reduced with rofecoxib compared with non-selective NSAIDs. Previous data have also shown a reduced incidence of falls in haemoglobin with rofecoxib and celecoxib, probably as a result of reduced whole gut blood loss. The size of our study means that differences were not statistically significant.

Consistent with previous studies, rofecoxib 50 mg was associated with a small increase in the incidence of physician reported adverse events of hypertension. A review of all hypertensive adverse events showed that these were generally of minor clinical impact and that most affected patients had pre-existing diagnoses of hypertension. No patient discontinued due to adverse events of hypertension; all patients continued on study drug and either had spontaneous resolution of their adverse event or had adjustment made to their non-study medications such that the hypertension was treated. No association between hypertension adverse events and untoward outcomes (for example, unstable angina, myocardial infarction, or cerebrovascular events) was observed. In the group as a whole, mean changes in blood pressure showed that changes in systolic or diastolic readings occurred early in the course of therapy and tended to be transient (resolving on treatment). It should be noted that these results were observed with a dose of rofecoxib that is twice the dose recommended for chronic treatment of RA.

In summary, the findings of this study demonstrated that treatment with rofecoxib 50 mg once daily was well tolerated in RA patients and resulted in lower incidences of endoscopically detected gastrointestinal ulcers and erosions compared with naproxen 500 mg twice daily.

H pylori infection and reflux oesophagitis

We read with considerable interest the paper by Kuipers et al (Gut 2004;53:5–7) which found no significant adverse impact on the severity of reflux disease or its control after two years of omeprazole therapy following H pylori eradication, during which time gastritis largely healed. In the commentary by McColl (Gut 2004;53:5–7), it is stated that although published data are conflicting, Schwizer et al reported improvement in reflux symptoms following H pylori treatment.1 Our preliminary published data,2 which are in accordance with those of Schwizer and colleagues,2 consisted of a small cohort of 69 patients with gastro-oesophageal reflux disease (GORD) and irritable bowel syndrome (IBS). Forty patients were treated with omeprazole (20 mg/day) plus trimethubine (600 mg/day) for three months (group A) and 29 were treated with omeprazole (20 mg/day) as monotherapy for an equal period of time (group B). During the eradication regimen, during which time gastritis was a statistically better response in patients who received omeprazole and the eradication regimen had GORD symptoms and 15 (62.5%) had histologically proven oesophagitis. Three months post-treatment, GORD was present in 12 (50%) patients (p<0.0001) and oesophagitis in nine (37.5%) (p<0.05). As improvement in oesophagitis did not reach a statistically significant level, our study was a statistical comparison. In our preliminary study, Barrett’s oesophagus was observed in eight (20%) of 40 and in five (17.2%) of 29 patients in groups A and B, respectively, similar to that (24.3%) observed by Kuipers et al. As there is an increased prevalence of IBS in patients with GORD,3 it would be interesting to know how many of the patients in Kuipers et al’s study had symptoms suggestive of IBS, and if their regimen had results similar to ours.

Our data show that H pylori is frequent in GORD and may contribute to the pathogenesis of GORD by several mechanisms.4 Also, we propose that the increasing prevalence of GORD may be partially explained not just by the decrease in prevalence of H pylori infection, as suggested by McColl (Gut 2004;53:5–7), but rather by healing of H pylori associated peptic ulcer disease, which coexists with GORD.5 Thus eliminating peptic ulcer disease unmasks GORD.6

In our latest unpublished data, 18 (48.6%) of 37 patients, in whom H pylori was eradicated, had reflux symptoms on omeprazole compared with four (50%) of eight patients in whom H pylori was not eradicated. Although the latter group was too small to draw definite conclusions, it seems that eradicating H pylori did not make GORD more difficult to control. While the editorial advocates that H pylori eradication makes it more difficult to achieve long term control of GORD with omeprazole therapy, we suggest that H pylori eradication leads to better control of GORD symptoms and improves oesophagitis.

Research trends in British gastroenterology: publication rates in newly appointed NHS consultants over a nine year period

It has been suggested that medical research within the UK may be in decline. Possible explanations for this could be the shortened training scheme created by the Calman Specialist Registrar (SpR) post, reduced availability of research funding, or the progressive expansion of the consultant body (as a government imperative to provide a consultant delivered service). Although this may be the perception, there has previously been no published evidence to demonstrate a reduction in research output. In this study, we wished to observe any overall trend in the number of publications and higher degrees that trainees (in gastroenterology) have at the time of their National Health Service (NHS) consultant appointments over a nine year period.

Participants, methods, and results

All consultant appointments and place of training were noted over a fixed period from February 1993 to April 2001 (courtesy of the British Society of Gastroenterology (BSG)). The BSG is considered to have a comprehensive list of its trainees and consultants. This has been used as a source for the prediction of manpower needs in gastroenterology. This model has subsequently been applied to other medical subspecialities. We cross referenced this source with the Medical Directory and BSG members’ handbook. We performed a PubMed and Embase search noting the number of publications of each consultant. This search included a lag time of up to 19 months post-appointment. This period has previously been described as the mean time from submission to publication. Higher degrees held by each consultant were also noted. Over the nine years, 349 appointments were made. We excluded consultant to consultant transfers and appointments to or from academic posts (n = 52). Also excluded were trainees who had subsequently left the UK or the medical register, as well as individuals where data were difficult to obtain due to name and centre similarities (n = 50). Statistical analysis was performed using Microsoft Excel to produce a linear regression line and correlation coefficient (r) to show the trend and strength of any relationship of the median publication rate over the time sampled. The nine years of medians gave 7 degrees of freedom (df = 7). We used χ² distribution to show any significant difference between the groups.

There was a year by year significant decreasing trend in the median number of publications obtained by a gastroenterology trainee at time of their appointment to an NHS consultant post. The total publication rate can act as a tool in assessing academic activity among trainees and could be extrapolated to all medical specialties.

There are limitations to our observations—publications may have been missed despite using Embase and PubMed. In addition, we excluded 50 consultants (50/349 = 14.9%) due to an inability to recognise their publication data or they were untraceable. We would not expect this omission to skew our results significantly due to the uniform proportional distribution of these individuals over the nine year period. It may be that they represent trainees who never published throughout their training. This would suggest even less overall academic activity than we have described.

Our data support the hypothesis that medical research (at least among NHS consultants) is in decline. Similar studies are required to validate this observation within other medical subspecialities (in the UK) and in other countries.

Prediction of oesophageal varices with platelet count/spleen diameter ratio or platelets alone

We read with great interest the article by Giannini et al on platelet count/spleen diameter ratio or platelets alone as predictors of oesophageal varices (Gut 2003;52:1200–5).

As the incidence of chronic liver diseases is growing, we are convinced that the development of non-invasive prediction tools to identify cirrhotic patients with oesophageal varices is of major interest. Several markers have been studied, and among them platelet count is commonly reported to be a good predictor of oesophageal varices. However, in the eight studies already published, their discriminative power was moderate, with
areas under the receiver operating curve (ROC) of 0.70 or less for platelets alone and for indexes combining platelets with other markers. Most of these studies included heterogeneous groups of patients, with compensated and decompensated cirrhosis.

In our unit, we performed prospectively platelet count and screening upper endoscopy on the same day in 41 patients with compensated cirrhosis and confirmed the moderate value of platelet count alone (AUROC = 0.70; Thabut, data not shown). The major drawback of platelet count is that it can depend on factors other than portal hypertension in cirrhotic patients. To avoid this bias, Giannini et al. developed an index based on platelet count/spleen diameter ratio and found far better results than previous studies, with a c index (equivalent to the area under the ROC) of 0.92 for patients with compensated liver cirrhosis. However, we were surprised to see that the use of platelets/spleen diameter ratio did not add significant discrimination to platelet count alone (c index of 0.92 ± 0.08) in their population.

On this point, their excellent results could not be explained by the discriminative power of the index but by the excellent diagnostic power of platelet count alone in their series. Several explanations can be raised, and one is the high rate of viral related cirrhosis in their patients where plate count is less liable to variations compared with, for example, in alcoholic patients. This point is of major concern for the further validation of their index, recommended by the authors themselves, in other populations.

In conclusion, Giannini et al. have found a very good index for predicting the presence of oesophageal varices in cirrhotic patients. We believe that the excellent results they obtained were not due to their index but to the surprisingly good performance of platelet count alone in their patients. Considering the results for platelet count as a predictor of oesophageal varices in previously published studies, we fear that the validated work of their index will show less exciting results.

Author’s reply

We thank Thabut et al. for their interesting comments on our paper (Gut 2003; 52:1200–5). Indeed, their letter allows us to focus on some aspects of our study that we feel need to be emphasised further.

As a general rule, a surrogate marker for a given variable (that is, presence/absence of oesophageal varices) has a definitive diagnostic procedure (that is, endoscopy) should fulfill two major criteria. Firstly, it should be the product of a thorough statistical analysis and secondly, but no less importantly, it has to be biologically plausible.

From a statistical point of view, as Thabut et al. correctly point out, both platelet count and the platelet count/spleen diameter ratio showed excellent diagnostic accuracy for the non-invasive diagnosis of the presence/absence of oesophageal varices. However, we do not agree with their assumption that the use of the platelet count/spleen diameter ratio did not add significant discrimination to the use of platelet count alone. In fact, the accuracy of the platelet count/spleen diameter ratio for the diagnosis of oesophageal varices was not only better than that of platelet count alone but was also significantly so. Briefly, in the cohort of 145 patients with compensated cirrhosis, which is the group that most likely benefits from screening, the difference between the AUC-ROC of the platelet count/spleen diameter ratio and platelet count was 0.041 (0.013–0.070), with p = 0.005 in favour of the platelet count/spleen diameter ratio. Moreover, in the whole cohort of 265 patients, the platelet count/spleen diameter ratio had a c index of 0.902 (95% confidence interval 0.860–0.935) while platelet count alone had a c index of 0.839 (0.790–0.881), with a difference between AUC-ROC of 0.053 (0.038–0.088) (p = 0.001). Furthermore, the platelet count/spleen diameter ratio was the only parameter significantly associated with the presence/absence of oesophageal varices in a multivariate analysis that also included platelet count. Lastly, as recently highlighted, the negative predictive power of a non-invasive parameter used to predict the absence/presence of oesophageal varices is a fundamental clinical concern. In fact, as a tool to be adopted in clinical practice it has to achieve a negative predictive value of 100% although maintaining an acceptable positive predictive value. This would preserve the safety of the parameter (thats is, virtual absence of missing a diagnosis) and keep a satisfactory cost-efficiency profile. In practice, to the study in our study in the use of the platelet count/spleen diameter ratio fulfilled these criteria while platelet count alone did not.

Biological plausibility is not a secondary concern for the clinician. As we emphasised in our paper and recently demonstrated, and as Thabut et al. also pointed out, the presence of thrombocytopenia in patients with liver cirrhosis is likely a multifactorial event. Therefore, the use of platelet count to diagnose a feature that depends on portal hypertension alone may lead to an increase in false positive results, thus decreasing the accuracy as well as the cost-effectiveness of the diagnostic procedure. As highlighted in our paper, the use of the platelet count/spleen diameter ratio could bypass this inconvenience by “normalising” platelet count to the platelet count decrease effectively dependent on hypersplenism. Lastly, some methodological issue should be taken into account when the two items of the ratio are singularly evaluated. On the one hand, the spleen diameter measurement should be performed by a skilled operator, and its results should have excellent accuracy and reproducibility. On the other hand, we have shown that the consistency of the ratio is maintained, even considering the expected mild fluctuations in platelet count commonly seen in cirrhotic patients during a limited period of time.

In all, we did not presume to propose a diagnostic “magic bullet”, as is more and more commonly being proposed in clinical hepatology. We are well aware that the results we obtained have to be validated in independent series and/or in cohorts with different aetiologies of liver disease before being widely accepted, and in our paper we clearly stated the limitations of our study. However, our patient population is that which we commonly encounter in everyday clinical practice, and it is not very different from that seen in other parts of our country (that is, viral cirrhosis in approximately 70% of patients). Moreover, if we look outside our borders, we see that our population is not very different from others, viral aetiology of liver disease being the leading cause of liver transplantation in Europe during the period January 1998 to December 2001 (22,924 cirrhotic patients). Nevertheless, if we examine our data we see that the use of the platelet count/spleen diameter ratio performs equally good in the limited subset of patients with alcoholic cirrhosis (n = 53, platelet count spleen diameter ratio c index = 0.958, platelet count c index = 0.740, difference between AUC-ROC = 0.218; p = 0.001), although we feel that focusing on a specific subgroup of patients that does not reflect the true prevalence of the disease in the population would introduce bias.

In conclusion, we have proposed a new evaluation tool and called for validation of our method, being conscious that only differences in opinion that arise from results obtained in well conducted studies contribute to scientific progress, and most importantly that “life is short, and art long; the crisis fleeting; experience perilsous, and decision difficult. The physician must not only be prepared to do what is right himself, but also to make the patient, the attendants, and externals cooperate.”

Computed tomography colonography: colon examination or Pandora’s box

We read with interest the article by Ginnerup Pedersen et al (Gut 2003;52:1744–7) investigating the diagnostic accuracy of colonography. Some concerns have been previously raised about colonography’s ability to detect extracolonic findings. The authors reported that a high proportion of patients (65%) are aware of the need for further workup. We would like to comment on the question raised by Ginnerup Pedersen et al—namely, whether colonography should be regarded as a colon examination or a sort of “Pandora’s box” (if used for abdominal screening).

Notably, a recent article has emphasised that one of the major potential advantages of MDCT colonography in comparison with all other existing colorectal diagnostic tests is its ability to detect disease outside the colon. Indeed, the possibility that extracolonic disease can be readily identified at CT colonography has been extensively investigated in the literature, with results similar to the ones presented by Ginnerup Pedersen et al. However, there is evidence that although the vast majority of extracolonic findings are of little clinical importance, such findings may lead to unnecessary further workup, with obvious economic, medicolegal, and psychological implications. Therefore, the possibility of “looking” outside the colorectal lumen can be seen as a “double edged sword” or “Pandora’s box”.

In this regard, we feel that three important issues need to be emphasised. Firstly, CT colonography is usually performed with a low dose technique which exploits the high contrast that exists at the colorectal mucosa-air interface. Such a low dose technique is adequate for evaluation of colorectal lesions but substantially limits the assessment of solid organs. In addition, there is a recent trend to reduce even further the radiation dose of CT colonography. For instance, the radiation dose in milliSieverts (mSv) is 10 mSv for standard abdominal CT, 6 mSv in the study of Ginnerup Pedersen et al, and 1.8–2.4 mSv in our hospital. Clearly, the lower the radiation dose, the lower the extracolonic diagnostic ability.

Secondly, in order to reduce the cost and increase the safety of the examination, CT colonography is usually performed without administration of intravenous contrast material. Clearly, this reduces even further the ability of CT colonography to detect and characterise extracolonic findings.

Thirdly, and perhaps most importantly, CT colonography has recently been demonstrated to be suitable for colorectal cancer screening purposes. However, there is no agreement regarding the use of standard abdominal CT for general abdominal screening. At present, abdominal CT screening is not supported by scientific evidence, the US Food and Drug Administration approval, or the American College of Radiology recommendation. It is clear that due to the use of a low dose technique and lack of intravenous contrast administration, CT colonography has even lower diagnostic ability than standard abdominal CT for assessment of disease outside the colon. Thus it is of paramount importance that radiologists, referring physicians, and patients are aware that CT colonography is not designed for the detection of extracolonic findings and should therefore be considered primarily as a colon examination. Due to the high prevalence of extracolonic abnormalities, radiologists should be alert to appropriate additional workup for triage patients to avoid opening a potential “Pandora’s box”.

Patients’ understanding of colonoscopy risk is suboptimal

We read with interest the British Society of Gastroenterology (BSG) lead audit by Bowles et al (Gut 2003;52:277–83) into colonoscopy practice within the UK. As part of the audit the authors questioned 1200 patients on their understanding of the procedure. The respondents, only 81.5% received written information, with only 54.9% recalling information on possible adverse events such as bleeding and perforation. The poor recollection of potential problems is perhaps to be expected if the audit questionnaire was sent to patients sometime after the procedure.

In common with many endoscopy units, we send out an information leaflet with the patient’s appointment details. This explains the preparation required, what to expect on the day, and any potential complications, with advice as to what to do should these complications arise. As there are concerns regarding potential medicolegal implications should complications related to endoscopy, we designed a short questionnaire to determine how much information patients were able to recall from the information leaflet sent to them prior to colonoscopy. This consisted of four multiple choice questions with five possible answers, of which only one was correct. The correct answers were all in the information leaflet. Patients were requested to complete the questionnaire just prior to discharge, at least one hour after procedure completion, thus minimising the effects of sedation. The questions related to: the risk of perforation; the degree of rectal bleeding that required medical assistance; what to do should a problem arise out of office hours; and the correct means of getting home after receiving sedation.

Thirty three patients completed the colonoscopy questionnaire and of these only 37% answered all four questions correctly. Only 52% of patients remembered correctly the perforation rate from diagnostic colonoscopy, which was stated as 1 in 1000 in our information leaflet. Worryingly, 12 patients (36%) thought that perforation rates were 10–100-fold lower than stated in the information leaflet.

Our study demonstrates that patients fail to fully appreciate the risks of colonoscopy despite the distribution of detailed written information prior to the procedure. This could have medicolegal implications should complications arise and intensifies the need for improved methods of informing patients.

British Society of Gastroenterology
Paul Brown Travel Fellowships

The Paul Brown Travel Fellowships are awarded by the Endoscopy Committee of the BSG. They are intended to assist trainee gastroenterologists and established consultants in visits to units outside the United Kingdom for specialist experience and training in endoscopy.

Specialist registrars who have not achieved their CCST are expected to have the approval of their Postgraduate Dean and their Regional Training Director when they apply for a Travel Fellowship. Applicants are expected to provide confirmation that they have been accepted for training in the unit that they wish to visit.

Successful applicants will be expected to provide a brief written report to the Endoscopy Committee of the outcome of their visit.

Application forms are available from the British Society of Gastroenterology Office, 3 St Andrew’s Place, London NW1 4LB. Email: bsg@mailbox.ulcc.ac.uk

European Postgraduate Gastro-surgical School (EPGS) Courses 2004

The EPGS at the Academic Medical Center of the University of Amsterdam will be holding the following courses during the year: ‘Endosonography live in Amsterdam’ will be held on 2, 3 & 4 June 2004, and ‘Update in Coloproctology’ will be held on 28 & 29 October 2004. For further information, please contact: J Goedkoop (tel: (31) 566 3926; fax: (33) 267 5994; e-mail: j.goedkoop@amc.uva.nl; website: www.epgs.nl).

8th Southeast European Symposium of Paediatric Surgery

The 8th Southeast European Symposium of Paediatric Surgery will focus upon ‘Infectious Problems in Paediatric Surgery.’ The event will be held between 24–25 September 2004, at the University of Graz, Austria. For further information, please contact: Professor M E Höllwarth, Department of Paediatric Surgery, Medical University of Graz, Austria, Auenbruggerplatz 34, 8036 Graz; tel: +43 316 385 3762; fax: tel: +43 316 385 3775; e-mail: kinderchirurgie@uni-graz.at.

12th European Symposium on Neurogastroenterology and Motility

The 12th European Symposium on Neurogastroenterology and Motility will be taking place at Robinson College, Cambridge, UK. The symposium will be taking place on 15–18 September 2004.

On Wednesday 15 September, there will be a postgraduate teaching day. This will cover established and evolving assessments of oesophageal, gastric and intestinal function, visceral sensitivity and brain responses. Basic science techniques including electrophysiology, imaging of gut movements and neural activation will be covered in the afternoon. Finally there will be a session on GI pharmacology covering cytokines, capsaicin and tachykinins.

On Thursday 16 September through to Saturday 18 September midday, the main meeting will be held. This will include symposia, oral free papers and poster rounds. The symposia will be designed to move from basic science to clinical practice and will include sessions on stress and the gut, appetite and obesity, serotonin and inflammation, and inflammation and GI motility. There will also be state of the art lectures and prize presentations.

For registration and further information, please see the website www.neurogastro.org, and follow links for ‘12th European Symposium on Neurogastroenterology and Motility.’ Please contact the conference organizers at: Confrex, PO Box 21, Rottingdean, East Sussex, BN2 8WZ (tel: +44(0)1273 302200; fax: +44(0)1273 302334; e-mail: confrex@easy.net.co.uk).

High magnification chromoscopic colonoscopy as a screening tool in acromegaly

We read with great interest the paper by Jenkins et al (Gut 2002;51:13–14) regarding screening guidelines for colorectal cancer (CRC) and polyps in patients with acromegaly and the subsequent discussion by Renehan addressing screening inconsistencies compared with other high risk groups.1

The optimal colorectal screening modality and frequency in this group however requires clarification. Colonoscopy in this patient group is technically demanding and often complicated by inadequate bowel preparation.2 However, despite current controversies regarding true CRC risk categorisation in acromegaly, previous data from the largest published series showed a trend for adenoma and carcinoma formation in the right hemi colon.3 This is an important observation for many reasons.

Flat adenomas and carcinomas can be difficult to detect by conventional colonoscopy alone, often presenting as subtle mucosal erythema, mucosal pallor, fold convergence, interruption of inorninate grooves, air induced deformation, or loss of vascular net pattern.4 The neoplastic risk for this morphologically distinct group has additionally been shown by many authors to be higher when compared with exophytic polyloid lesions and exhibit a propensity for the right colon.5,6 De novo neoplastic lesions and “minute” colorectal cancers are also associated with an increased risk of lymph node metastasis due to early invasion of the submucosal layer.7 Tada et al found extensive submucosal invasion in a cohort of flat colorectal neoplasms,8 with Shimoda’s series corroborating these data with submucosal invasion demonstrable in 69% of flat carcinomas compared with only 35% of sessile and broad based polyoid carcinomas.9

Morphologically flat and depressed lesions are also known to occur in chronic ulcerative colitis10 where the need for CRC screening with total colonoscopy and now adjunctive chromoendoscopy is adopted by many centres. Failure to detect such lesions may in part account for those cases of CRC which occurred in Winawer’s study, despite clearance of all exophytic polyps, and thus stresses the requirement for accurate diagnosis and definitive treatment of these high risk lesions.11

Given the lack of standardisation and uniform reporting regarding the morphology of colorectal lesions in many of the existing prevalence studies of adenomas and CRC in acromegaly however, at present we can only hypothesise that the high incidence of right hemi colorectal neoplasia may be an indicator of an alternative morphologically distinct lesion such as the flat adenoma and carcinoma with a trend towards a de novo pathogenic sequence.

In our prospective study, 38 patients with acromegaly underwent total colonoscopy by a single endoscopist using the Olympus C240Z magnifying colonoscope. Preparation was with 4 litres of Kleanprep 24 hours prior to the procedure. Pancolonic chromoscopy using 0.5% indigo carmine sprayed onto the colonic mucosa using an Olympus diffusion catheter (CS12890) was applied. Identified lesions were morphologically grouped according to the Japanese Research Society Classification (JRSC).12 A flat lesion was defined as mucosal change with a flat or rounded surface combined with a height of less than half the diameter of the lesion.13 High magnification views of all suspected lesions were then obtained and reported according to the modified Kudo criteria.14 Tissue sampling was performed with cold biopsy or endoscopic mucosal resection following exclusion of a Kudo type Y(n)/III lesion.15 Invasive crypt pattern which suggests deep submucosal invasion. Mean intubation and extubation times were recorded. Neoplastic change was classified according to the Vienna criteria.16

Caecal intubation was achieved in 37/38 (97%) patients with 36/38 (94%) receiving confirmatory terminal ileal biopsies. Males represented 14/37 (37% of the cohort, mean age 64 years (range 40–75)). The mean duration of intubation to the caecum was 16.5 minutes (range 3–31) and extubation (excluding interventional procedures) was 35 minutes (range 20–55). There were no complications.

A total of 28 lesions were identified in 15 patients. Twenty two hyperplastic lesions were identified (79%) of which 17 (77%) were flat (JRSC II). Twenty (91%) were located in the left colon and rectum. Of the five adenomas identified, four (80%) were present in the right colon with 4/5 (80%) being of JRSC II morphology. A single adenoma with high grade dysplasia was present in the right colon and was flat with a small area of central depression. No invasive carcinomas were diagnosed. Results are summarised in table 1.

Although the numbers entering this study are small, our results show a clear prevalence for JRSC class II lesions in this select patient group. Although only one adenoma with high grade dysplasia was detected, it was small (5 mm) and was not identified prior to chromoscopic and magnification enhancement, and therefore carries major clinical connotations.

We suggest that further large prospective studies are required to establish the true prevalence of flat and depressed colorectal lesions in acromegaly so that the optimal screening modality and frequency can finally be established. Furthermore, colonoscopists require training in chromoscopic techniques if a higher endoscopically “treatable” lesion frequency is to be detected at a screening level, so as to avoid the high apparent incidence of interval neoplasms.

Fetal “cardiac mucosa” is not adult cardiac mucosa

De Hertogh et al’s autopsy study of the fetal gastro-oesophageal region provides valuable insight into the development of forcut epithelium in the 13–24 week gestational period (Gut 2003;52:791–6). Coincidentally, two other studies appeared on the same subject in April 2003.1,2 These studies were stimulated by our hypothesis that cardiac mucosa does not exist as a normal structure in any adult. Three columnar epithelial types are reported between squamous epithelium and parietal cell containing gastric mucosa in De Hertogh’s study (Gut 2003;52:791–6). These are: “primitive oesophageal mucosa”, “primitive stomach mucosa”, and “cardiac mucosa”. Careful anatomical correlation place all of these mucosae in the oesophagus, proximal to the gastro-oesophageal junction. “Primitive oesophageal mucosa” is a ciliated epithelium that appears transiently at about 24 weeks. “Proximal stomach mucosa” is a layer of flat columnar cells containing depressions that correspond to early gland pits distally. “Cardiac mucosa” is composed of foveolar and surface epithelium overlying glandular structures containing no parietal cells. The description of “cardiac mucosa” and figs 2 and 4 show a very thin columnar epithelium composed of uniform mucous cells with foveolar pits and rudimentary sac-like structures devoid of any inflammation. Derdoy et al’s “cardiac mucosa”4 and Park et al’s “transition zone”5 are identical in appearance. I have never seen this fetal epithelium in any adult patient. The fact that these authors call it “cardiac mucosa” does not make it identical to the more conventional cardiac mucosa seen in adults. The only similarity is that it is a glandular mucosa composed of mucous cells only. It is much thinner than adult cardiac mucosa, it has no inflammation, and its glands are much less developed if present at all. I would like to propose an alternate explanation for the changes seen in all three papers that provides a better explanation of the data in the papers. The early fetal oesophagus is lined by primitive undifferentiated ciliated columnar epithelium. It begins differentiating into squamous epithelium proximally and gastric mucosa distally. Gastric differentiation is marked by the appearance of true glands containing parietal cells. In the second trimester, the oesophageal squamous epithelium is separated from the developing gastric mucosa by a columnar epithelium composed of forcut columnar stem cells forming a flat surface and a foveolar pit. This is uncomplicated fetal columnar epithelium. This continues to develop into either squamous epithelium proximally or parietal cell containing gastric mucosa distally. The overall length decreases as fetal age increases (as shown in De Hertogh et al and Derdoy et al’s studies).5,4 With the regression of the lower oesophageal sphincter in early infant life, the physiological gastro-oesophageal junction is defined and the uncomplicated columnar forcut epithelium completes its differentiation into squamous in the oesophagus and gastric mucosa with parietal cells distal to the lower oesophageal sphincter. The uncomplicated forcut columnar epithelium disappears. The only normal mucosa seen after development is complete are squamous and gastric with parietal cells. This is proven by illustrations that show children with a direct transition of squamous epithelium to gastric mucosa with parietal cells (Chandrasoma’s studies5 and fig 2A of Park and colleagues4). The absence of cardiac mucosa in these illustrations is proof that cardiac mucosa is not universally present in children. Adult-type cardiac mucosa is also absent universally in fetuses. The only reason why De Hertogh et al reach the conclusion that it is universally present in fetal life is that they erroneously apply the term “cardiac mucosa” to the uncomplicated fetal columnar epithelium that is universally present in fetal life.

References

Author’s reply
We would like to thank Dr Chandrasoma for his informative reading and kind comments on our work published in Gut. He has also provided the readers with an admirable synthesis of the most recent research on the development of the different mucosal types in the gastro-oesophageal junction region. By means of this letter, we want to reflect on some of his comments.

The quintessence of Dr Chandrasoma’s vision on cardiac mucosa (CM) is that it is not a normal structure but rather an abnormal metaplasia in the context of gastro-oesophageal reflux disease. The presence of a small length of CM in many “normal” adults could be the result of asymptomatic low level reflux. According to his theory, “non-committed non-glandular late fetal forcut epithelium”4 (which we call CM in our study) will develop into either oesophageal squamous epithelium or gastric mucosa with parietal cell containing glands. The necessary corollary of his theory is that there can be no such thing as a normal CM. He also puts forward the notion that the presence of CM in some infants might be due to deviant differentiation of the uncomplicated epithelium in the context of reflux or other trauma such as nasogastric intubation. Even if this hypothesis is correct, I think that other possibilities should be considered. One possible situation could be the persistence of the uncomplicated epithelium with development of a sort of heterotropic CM (analogous to the heterotopic fundic-type mucosa described in the upper third of the oesophagus). Clearly, more research is needed for future research. As Dr Chandrasoma himself says, the most important reason for the divergent conclusions of his work and ours are the terminology and interpretation of the data. What we call CM, is, in Dr Chandrasoma’s opinion, an uncomplicated epithelium devoid of glands. He specifically warns against applying the designation “gland” to the tangentially cut tortuous ends of the foveolar pits (our fig 2 and fig 4). We believe glands are present in these illustrations. We formed this conclusion both on a purely morphological basis (the gland cells are cuboidal to triangular and contain a centrally located round nucleus) and after histochemical evaluation (the foveolar and pit cells contain a large amount of mostly neutral mucins, whereas the columnar cells contain a long time contain only a small amount of mostly acidic mucins). We used the term CM

P T Chandrasoma

for this zone interposed between squamous and fundic mucosa because of its morphological analogy with adult CM (whether normal or abnormal). Its principal characteristic is the presence of mucus producing glands devoid of parietal cells. We stated that CM develops during gestation and is present at birth. We do not know what happens with this entity in infants and children. We cannot comment on the identity of adult CM: has it always been there or did it develop through metaplasia? To prove or disprove Dr Chandrasoma’s theory, evidently much further research has to be done.

**Helicobacter pylori infection in Africa and Europe: enigma of host genetics**

*Helicobacter pylori* infection is one of the most common bacterial infections. The prevalence varies from 25–50% in developed countries to 70–90% in the third world. Despite improved treatment modalities, *H pylori* related gastrointestinal pathology, in common with gastric, peptic ulcers and consecutive bleeding events, gastric MALT lymphoma, or carcinoma, remains a major burden on Western health systems. In the USA, approximately four million people have active peptic ulcers and another 350,000 new cases are diagnosed each year. Four times as many duodenal ulcers as gastric ulcers are diagnosed.

Epidemiological evidence suggests that both infection with *H pylori* and the consecutive development of clinically relevant pathology are influenced by genetic predisposition as well. The prevalence of *H pylori* infection is one of the most significant risk factors for the development of clinically relevant pathology, in common with gastrointestinal pathology, in common with gastric, duodenal, or jejunal ulcers, as suggested pathophysiologically by Mitchell et al., who demonstrated major differences in the IgG subclass response to *H pylori* infection in the first and third world. In relation to clinical disease manifestations, the IFNGR1 locus may affect antibody concentrations but not the clinical course of *H pylori* infection in Caucasians. Alternatively, other immunoregulatory genes in the vicinity of the IFNGR1 locus such as the interleukin 20 receptor α (200 kb distance) or MAP kinases 5 (600 kb distance) could harbour the causative variants. High-density LD mapping of the locus is required to unravel the causative genetic variants in both African and Caucasian populations. Our data support the hypothesis that the genetic diversity of the host immune system may contribute to the differences in *H pylori* clinical outcome and prevalent clinical outcomes in African and Caucasian populations.

**Platelet activation in patients with irritable bowel syndrome may reflect a subclinical inflammatory response**

We read the recent article by Houghton et al and found the results very interesting (Gut 2003;52:663–70). Their observations included higher platelet concentrations of 5-hydroxytryptamine among patients with irritable bowel syndrome (IBS) compared with controls. It is interesting that a small but significant subgroup of IBS patients report onset of their symptoms after an episode of acute gastroenteritis and a role of subclinical inflammatory aetiology has been suggested for the condition. The role of platelets in various inflammatory conditions has previously been demonstrated but their importance in IBS remains largely unknown. We recently looked at the possibility of platelet activation in IBS patients by determining surface expression of the activation markers at baseline and after stimulation. Stimulation was involved in the use of thrombin receptor activating peptide (TRAP), activation markers P-selectin (CD62) and glycoprotein 53 (CD63), and glycoprotein (GP) receptors GPIb-IX and GPIb-V-IIIa and GPIIIa, using whole blood flow cytometric analysis (Becton Dickinson Flow Cytometer). Twenty consecutive IBS patients (18 females), mean age 29 years (22–62), fulfilling the Rome II criteria (90% d-IBS) and 15 healthy controls (11 females), mean age 28 years (22–49), were included. Raised inflammatory markers, previous bowel dis-

**Table 1** Haplotype analysis of infection status and clinical manifestation of *Helicobacter pylori* infection

</table>

The table shows the comparative frequencies of the IFNGR1 haplotype described above. Susceptibility to *H pylori* infection was tested by comparison of all *H pylori* positive patients (n; all subgroups: 66+112+166=344) against normal controls (top row). Genetic predisposition for complications of *H pylori* infection was tested by comparison of patients with gastric pathology (gastric or duodenal erosions, n=66) and severe pathology (gastric or duodenal ulcers n=112) against patients with mild or no pathology grouped together (no pathology, gastritis, or duodenitis, n=166).

Significance was assessed by a 2 × 2 test of the global likelihood ratio of the case control haplotype estimations.
Baseline expression of P-selectin was significantly increased in the IBS group (median 5.9 (interquartile range (IQR) 4.4–8.9)) compared with healthy controls (median 4.1 (IQR 3.2–5.9)) (p = 0.03), all values representing per cent expression. Baseline expression of GP33 was higher in the IBS group (median 3.0 (IQR 1.9–4.0)) compared with normal controls (median 2.3 (IQR 1.9–2.8)) but failed to reach clinical significance. TRAP stimulation resulted in increased expression of P-selectin and GP33 in both groups.

Glycoprotein reactivity post stimulation was significantly lower in the IBS group compared with normal controls (p<0.05).

The numbers of GPIb/IIa and GPIb-IX receptor sites on the platelet surface for each group were calculated using a calibration curve where MFI and the corresponding number of antibody sites of multiple bead populations were plotted using a log log curve where MFI and the corresponding number of antibody sites of multiple bead populations were plotted using a log log curve.
