Live probiotics protect intestinal epithelial cells from the effects of infection with enteroinvasive *Escherichia coli* (EIEC)

S Resta-Lenert, K E Barrett

**Background:** The colonic epithelium maintains a life long reciprocally beneficial interaction with the colonic microbiota. Disruption is associated with mucosal injury.

**Aims:** We hypothesised that probiotics may limit epithelial damage induced by enteroinvasive pathogens, and promote restitution.

**Methods:** Human intestinal epithelial cell lines (HT29/cl.19A and Caco-2) were exposed to enteroinvasive *Escherichia coli* (EIEC O29:NM), and/or probiotics (Streptococcus thermophilus (ST); ATCC19258, and Lactobacillus acidophilus (LA), ATCC4356). Infected cells and controls were assessed for transepithelial resistance, chloride secretory responses, alterations in cytoskeletal and tight junctional proteins, and responses to epidermal growth factor (EGF) stimulation.

**Results:** Exposure of cell monolayers to live ST/LA, but not to heat inactivated ST/LA, significantly limited adhesion, invasion, and physiologic dysfunction induced by EIEC. Antibiotic killed ST/LA reduced adhesion somewhat but were less effective in limiting the consequences of EIEC invasion of cell monolayers. Furthermore, live ST/LA alone increased transepithelial resistance, contrasting markedly with the fall in resistance evoked by EIEC infection, which could also be blocked by live ST/LA. The effect of ST/LA on resistance was accompanied by maintenance (actin, ZO-1) or enhancement (actinin, occludin) of cytoskeletal and tight junctional protein phosphorylation. ST/LA had no effect on chloride secretion by themselves but reversed the increase in basal secretion evoked by EIEC. EIEC also reduced the ability of EGF to activate its receptor, which was reversed by ST/LA.

**Conclusions:** Live ST/LA interact with intestinal epithelial cells to protect them from the deleterious effect of EIEC via mechanisms that include, but are not limited to, interference with pathogen adhesion and invasion. Probiotics likely also enhance the barrier function of naïve epithelial cells not exposed to any pathogen.

**Abbreviations:** ST/LA, *Streptococcus thermophilus* and *Lactobacillus acidophilus*; EIEC, enteroinvasive *Escherichia coli*; TSA, trypticase soy agar; MRS, deMan Rogosa Sharpe broth; PMN, polymorphonuclear leucocytes; EGF, epidermal growth factor receptor; EGF, epidermal growth factor receptor; MOI, multiplicity of infection; CFU, colony forming unit; PBS, phosphate buffered saline; FS, fluorescein sulphonic acid; FITC-D10, fluorescein isothiocyanate-dextran-10S; Isc, short circuit current.
pathogens increases both basal and stimulated chloride secretion and decreases barrier function by rearranging cytoskeletal and tight junctional proteins.21,22

In this study, we hypothesised that pretreatment of epithelial cells with probiotics may protect them from the deleterious effects of subsequent infection with an enteroinvasive pathogen, and sustain recovery of the epithelium by promoting continued EGFr signalling. The aim of this study therefore was to investigate the effects of a combined preparation of two probiotic bacteria, *Streptococcus thermophilus* (ST) and *Lactobacillus acidophilus* (LA), on intestinal epithelial cell physiology. We hoped to provide a rationale for the use of probiotics as therapeutic and preventative agents, at least in infectious diarrhoea, and perhaps also in diseases associated with acute or chronic inflammation of the gut.

**MATERIALS AND METHODS**

**Cells**

HT29/cl.19A and Caco-2 cells were cultured as previously described.23 Data obtained with both cell lines were qualitatively identical and have been used interchangeably in the results section. Briefly, cells were grown in McCoy's medium (Cellgro; Fisher, Philadelphia, Pennsylvania, USA) supplemented with 10% fetal calf serum, and maintained in an atmosphere of 5% CO2-95% O2, at 37°C. Cells were used between passages 5 and 25, and grown in 75 cm² flasks (Costar, Cambridge, Massachusetts, USA), HA Millipore filter inserts (12 and 24 mm diameter; Millipore, Bedford, Massachusetts, USA), or glass chamber slides (Nalge Nunc, Rochester, New York, USA). Cells grown as polarised monolayers on filters reached confluence in 7–8 days and were used consistently within 14 days from seeding, or five days post confluence.

**Bacteria**

Enteroinvasive *Escherichia coli* (EIEC O29:NM), non-invasive *S thermophilus* (ST), and *L acidophilus* (LA, ATCC4356) were obtained from ATCC (Rockville, Maryland, USA), *S thermophilus* (ST, ATCC19258), and *L acidophilus* (LA) from LA were routinely cultured under microaerophilic conditions. Enteroinvasive *E coli* (EIEC) (EIEC O29:NM) and *S thermophilus* (ST) were obtained from ATCC (Rockville, Maryland, USA), or glass chamber slides (Nalge Nunc, Rochester, New York, USA). Cells grown as polarised monolayers on filters reached confluence in 7–8 days and were used consistently within 14 days from seeding, or five days post confluence.

**Cell infection/treatment and intracellular survival assay**

Confluent epithelial cell monolayers were treated with serum free medium containing exponentially grown bacteria at a multiplicity of infection (MOI) of 50:1 to the apical surface. After one hour at 37°C, cells were washed and incubated in serum free medium with gentamicin (50 μg/ml) for cells infected with invasive bacteria or uninfected controls or in medium alone (for cells treated with probiotics) for one hour at 37°C. In control experiments, gentamicin had no effect on any of the parameters measured. Furthermore, no significant bacterial overgrowth was observed over the duration of the experiment under all conditions tested. In some experiments, cell monolayers were pretreated with ST/LA for one hour prior to infection with EIEC, as described above, and subsequent killing of extracellular bacteria with gentamicin. Some experiments were performed using probiotics that had either been killed with antibiotics (quinupristin/dalfopristin and vancomycin, 4 μg/ml, for one hour at 37°C) or heat inactivated (one hour at 100°C). Spent and filtered (0.2 μm), lyophilised, and concentrated (10x), supernatants from S/LA cultures were also used in some experiments. Cells were then maintained at 37°C, 5% CO2 in serum and antibiotic free medium. All treated monolayers had 50% of the culture medium changed every 24 hours after infection to avoid detrimental effects from nutrient utilisation and/or variations in pH. Cell invasion and bacterial survival were checked between three and 48 hours after infection to test the reproducibility of the infection protocol. Cell lysates and supernatants from treated monolayers and controls were checked by colony forming unit (CFU) counts on TSA or MRSA agar (MRSA).

**Adherence assay**

Bacteria from log phase growth cultures were washed twice in phosphate buffered saline (PBS), pelleted by centrifugation, and suspended at a concentration of 1x10⁸ CFU/ml in cell growth medium. Bacterial suspension (1 ml) was diluted in 1 ml of cell growth medium and the suspension overlaid on cells grown on glass slides. The treated cells were then incubated at 37°C for 1–3 hours in an atmosphere of 5% CO2-95% O2. After incubation, cells were washed with PBS, fixed in absolute methanol, Gram stained, and observed by light microscopy. Adherence of EIEC was measured by counting Gram negative bacteria per 100 cells in 20 random microscopic fields.

**Bacterial interference assay**

Bacterial interference was quantified by a plate dilution method. Briefly, epithelial monolayers were exposed to ST/LA at 50:1 MOI for various times. Cells were then washed with warm PBS and exposed to EIEC (100:1 MOI) for one hour and subsequently tested for cell associated EIEC after hypotonic lysis using sterile distilled water supplemented with 0.1% bovine serum albumin for 30 minutes on ice. Cell associated enteropathogens were defined as adherent plus intracellular bacteria and quantified by CFU counts of diluted cell lysates on TSA agar. To quantify only intracellular bacteria, parallel cell monolayers were exposed to serum free medium supplemented with 50 μg/ml gentamicin for one hour at 37°C after infection with EIEC, in the presence or absence of ST/LA pretreatment, then washed and lysed as described above. EIEC invasion was expressed as a percentage of intracellular bacteria compared with total cell associated bacteria. Probiotic interference was assessed by quantitating EIEC invasion in the presence and absence of probiotic pretreatment.

Electrophysiological studies

Infected and non-infected cell monolayers were tested for chloride secretion in modified Ussing chambers at various times after infection, as described previously.54 Transepithelial resistance (TER) was measured at the time points indicated. Resistance values of cell free inserts were subtracted from each measurement. Data are means (SEM), n=10. Where error bars are not shown, they are obscured by the symbols. *p<0.05, **p<0.01, ***p<0.001 compared with uninfected controls (by ANOVA).

Permeability assay

Polarised cell monolayers were pretreated with probiotics for one hour, infected with EIEC as described above, and harvested after incubation at 37°C in 5% CO₂ atmosphere for 12 hours. Fluorescein sulphonic acid (FS; Molecular Probes, Eugene, Oregon, USA; molecular weight 10 000, 20 mg/ml) was added to the basolateral side. Dishes were incubated at 37°C in a 5% CO₂ incubator for one hour with gentle mixing at 15 minute intervals. After the initial incubation, at 15 minute intervals up to two hours thereafter, the FS and FITC-D10 content of apical (Ap) and basolateral (Bl) samples was measured as fluorescence intensity of 1:250 dilutions in distilled water (492 nm excitation and 515 nm emission wavelengths). Monolayer permeability was expressed as FS or FITC-D10 clearance: [FS]₆₀-[FS]₅₆/[FS]₅₆, corrected for insert area (nl/cm²/h). A standard curve using incremental concentrations of FS or FITC-D10 was constructed for each assay.

Immunoprecipitation and immunoblot analysis

Infected and uninfected cells grown on 24 mm diameter Millipore HA filters were harvested at various times after infection and processed as previously described.65 Proteins of interest were immunoprecipitated by overnight incubation at 4°C on a mixer with an appropriate dilution of specific antibody (anti-ZO-1, anti-claudin, and anti-tight junction from Santa Cruz Biotechnology, California, USA; anti-phosphatidylserine, anti-EGFr, and anti-ERK 1,2 from Transduction Laboratories, Lexington, Kentucky, USA) in cold lysis buffer65 supplemented with additional phenylmethylsulphonyl fluoride (20 μM). Samples were then incubated with protein A agarose at 4°C for one hour with constant mixing. After washing, the immunoprecipitated proteins were electrophoresed on 7.5% or 4.5–15% polyacrylamide gels (BioRad, Hercules, California, USA) and transferred onto blotting membranes (Polyscreen PVDF; NEN, Boston, Massachusetts, USA). After overnight blocking (PBS/5% dried milk supplemented with 1% non-fat dry milk), blots were incubated with primary and secondary antibodies (horseradish peroxidase conjugated antimouse IgG, antirabbit IgG, or antiphosphotyrosine, as appropriate) for 60 minutes at room temperature. Proteins were visualised by chemiluminescence reagents (ECL Plus, Amersham, Piscataway, New Jersey, USA) and exposed to X-OMAT film (Eastman Kodak, Rochester, New York, USA).

Chemicals

Unless otherwise indicated, all chemicals were of reagent grade and were obtained from Sigma.

Data analysis

All data are expressed as means (SEM). Statistical analysis was performed by repeated measures ANOVA and p values <0.05 were considered statistically significant.

RESULTS

Effects of probiotic colonisation on intestinal epithelial cell barrier function

To investigate any direct effects of probiotics on our cell line models, we selected ST and LA, and exposed HT29/cl.19A and Caco-2 cells to each individual strain and to a combination of the two (ST/LA). The two probiotics were not toxic to the cell monolayers, as shown by viability measurements (trypan blue exclusion assay, and HO342 and rhodamine fluorescence staining) following incubation with various MOI (10–5000:1) of bacteria for up to 48 hours compared with untreated controls (data not shown). Furthermore, no significant bacterial overgrowth was observed over the duration of the experiment under all conditions tested. Moreover, neither strain altered the basal chloride secretory function of intestinal epithelial cells (not shown). In contrast, the combination of the two probiotics caused a small but significant increase in TER (fig 1A). This effect on TER was also corroborated by the effect of ST/LA on permeability of infected monolayers to the small molecular tracer FITC (table 2). However, neither ST or LA, nor both strains in combination, altered permeability to a 10 kDa tracer (table 2). Spent medium from ST or LA cultures, ST/LA killed with antibiotics (fig 1B), and heat inactivated probiotics failed to increase TER or decrease permeability to FITC (not shown). We conclude that live probiotics improve epithelial barrier properties. This is a potential mechanism contributing to their beneficial effect in vivo.
Pretreatment with probiotics prevents EIEC induced decrease in TER

We and others have previously shown that a prominent effect of invasive pathogens is to reduce TER.\(^7\) Because probiotics alone improved epithelial barrier function, we next explored whether they might also abrogate the deleterious effects of pathogens on this parameter. HT29/cl.19A (fig 2A) or Caco-2 (not shown) cells were exposed to medium alone, to ST/LA and EIEC, or to EIEC or ST/LA alone. Probiotic treatment consisted of live bacteria, antibiotic killed, or heat inactivated preparations. EIEC caused a decline in TER beginning at 6–12 hours after infection compared with uninfected control monolayers whereas pretreatment with live probiotics prevented this effect. The EIEC evoked fall in TER was also partially attenuated if cell monolayers were exposed simultaneously to probiotics and EIEC, but not if the cells were infected with EIEC for one hour and then exposed to ST/LA alone. Moreover, even at higher MOI, simultaneous addition of probiotics failed to prevent permeability changes induced by EIEC alone, ST/LA alone, or EIEC followed by ST/LA at equivalent MOI, or exposure of the cell lines whereas antibiotic killed or heat inactivated ST/LA preparations of living (A), antibiotic killed (B), or spent medium (SM) from ST and LA cultures (B) were tested in these experiments. TER was measured at the times indicated. Resistance values of cell free inserts were subtracted from each measurement. Data are means (SEM), n=8. *p<0.05, **p<0.01, ***p<0.001, clearance values significantly different from corresponding control values (by ANOVA).

Pretreatment with probiotics increases EIEC induced permeability to small molecules and macromolecules

The effects of EIEC, with or without probiotics, on TER measurements was suggestive of corresponding effects on epithelial permeability. To examine this directly, we measured the flux of two fluorescent probes of differing size across infected and control monolayers. After infection with EIEC, the permeability of HT29/cl.19A and Caco-2 cells, expressed as clearance of the two fluorescent probes tested, was markedly increased and the alteration was proportionally greater for the smaller probe (table 2). Moreover, pretreatment only with live probiotics prevented the increase in permeability induced by EIEC infection for up to 24 hours after EIEC exposure in both cell lines whereas antibiotic killed or heat inactivated ST/LA failed to exert this effect. Furthermore, simultaneous inoculation of ST/LA and EIEC at equivalent MOI, or exposure of the cells to probiotics one hour after EIEC infection, also failed to prevent the increase in FS or FITC-D10 permeability (table 2). Moreover, even at higher MOI, simultaneous addition of probiotics failed to prevent permeability changes induced by EIEC despite the fact that this treatment reduced EIEC invasion (see below).

Figure 2 Pretreatment with probiotics prevents enteroinvasive Escherichia coli (EIEC) induced decrease in transepithelial resistance (TER) of polarised HT29/cl.19A cell monolayers. HT29/cl.19A cells were exposed to medium, EIEC followed by Streptococcus thermophilus and Lactobacillus acidophilus (EIEC+ST/LA), EIEC and ST/LA given simultaneously (EIEC/ST/LA), EIEC alone, ST/LA followed by EIEC (ST/LA+EIEC), or ST/LA alone on the apical side. Preparations of living (A), antibiotic killed (B), heat inactivated (I), or spent medium (SM) from ST and LA cultures (B) were tested in these experiments. TER was measured at the times indicated. Similar findings were observed in Caco-2 cells.

Pretreatment with probiotics limits colonisation of EIEC in epithelial cell monolayers

We next explored whether our probiotic preparation altered the interaction of EIEC with the epithelium. As shown in table 3, the number of adhered EIEC was significantly reduced when monolayers were preincubated with equal numbers of each of ST and LA. Moreover, if the relative numbers of the probiotic strains were increased while the EIEC inoculum remained constant at 50:1, adhesion of EIEC was essentially abolished, particularly at later time points. Simultaneous addition of probiotics and EIEC was also able to inhibit adhesion of the latter bacteria, although only with an increased number of probiotics and to a lesser extent than seen with preincubation. In contrast, if probiotics were added one hour after EIEC infection, no significant effect on EIEC adhesion was seen. Interestingly, antibiotic killed ST/LA maintained the ability to inhibit EIEC adhesion, whereas heat inactivated probiotics or spent medium did not (table 3).

Pretreatment with probiotics prevents disruption of cytoskeletal and tight junctional protein localisation and phosphorylation

The ability of probiotics to reduce effects of EIEC on TER suggest that probiotics may modify the cytoskeleton and tight junctions. We analysed the phosphorylation status and abundance of selected cytoskeletal and tight junctional proteins, as summarised in fig 4A and 4B. Infection with EIEC caused a significant reduction in serine phosphorylation of occludin (fig 4A) and tyrosine phosphorylation of ZO-1 (fig 4B), without a major change in the abundance of these proteins. These effects were completely prevented if cells were pretreated with live probiotics prior to EIEC infection (fig 4). Simultaneous treatment with probiotics had a significant effect only at MOI ≥10:1 (data not shown). Similarly, EIEC significantly reduced tyrosine phosphorylation of actinin (fig 5), an effect shown elsewhere to correlate with disruption of actin filaments. Again, this deleterious response was reduced by live probiotic pretreatment or simultaneous treatment at high MOI (103:1), but not by antibiotic killed ST/LA (fig 5). These data emphasise the multiplicity of interactions of probiotic ST/LA in our model, and underscore the complex correlation between barrier function and cytoskeletal and tight junction homeostasis in the intestinal epithelium. Again, they also imply that invasion of EIEC is needed to effect changes in tight junction proteins.

Pretreatment with probiotics limits ion transport dysfunction associated with EIEC infection of epithelial cells

We have previously shown that enteroinvasive bacteria increase basal chloride secretion by intestinal epithelial cells. Furthermore, infection with enteroinvasive bacteria alters the expression and abundance of specific transport proteins. To test if probiotics prevent these effects, we measured Lb, an indicator of chloride secretion, in Ussing chambers. As shown in fig 6A, and as expected on the basis of previous studies, through multiple levels of interaction with host cells and invading organisms.
Pretreatment with probiotics significantly reduces enteroinvasive Escherichia coli (EIEC) invasion of infected Caco-2 cell monolayers. (A) Caco-2 cells were exposed to EIEC alone, *Streptococcus thermophilus* and *Lactobacillus acidophilus* followed by EIEC (ST/LA+EIEC), ST/LA and EIEC simultaneously (ST/LA/EIEC), or EIEC followed by ST/LA (EIEC+ST/LA), and treated with gentamicin one hour after EIEC infection to kill extracellular bacteria. Living, antibiotic killed (*), and EIEC simultaneously (ST/LA/EIEC), or EIEC followed by ST/LA (EIEC+ST/LA), and treated with gentamicin one hour after EIEC infection to kill extracellular bacteria. Living, antibiotic killed (*), and heat inactivated (†) ST and LA were tested in these experiments. Cell lysates were plated on agar for colony forming unit (CFU) counts in the experiments shown. (B) (pretreatment) and (C) (simultaneous treatment) summarise invasion data obtained at various ST/LA multiplicity of infection (MOI) (EIEC 50:1 MOI). (D) Results of invasion in cell monolayers pretreated with inactivated probiotics plus their spent medium (SM) or spent medium alone. Data are means (SEM), n=6. *p<0.05, **p<0.01, ***p<0.001 compared with cells infected with EIEC in the absence of probiotics (by ANOVA).

EIEC induced a significant increase in basal Isc, compared with untreated controls and ST/LA treated cells as early as 1–3 hours after infection. Furthermore, pretreatment with ST/LA completely prevented the effect of EIEC infection on Isc. However, even much higher MOIs of probiotics (>10⁷ CFU) failed to limit EIEC induced alterations in baseline Isc if the probiotics were added simultaneously with or one hour after EIEC (not shown) despite reduced colonisation in the former case. Furthermore, if the probiotic preparation was killed by pretreatment with antibiotics, ST/LA failed to induce any significant protective effect against increased baseline Isc in monolayers infected with EIEC. On the other hand, spent medium from ST/LA cultures plus an antibiotic treated probiotic inoculum, although not heat inactivated, ST/LA plus spent medium, partially reversed the increased basal Isc of EIEC infected monolayers if added simultaneously with the enteropathogen (fig 6B). This stands in considerable contrast with failure of spent medium to reverse effects of EIEC on other epithelial parameters discussed previously, or to prevent EIEC adhesion. This underscores the fact that probiotics alter responses to pathogens via numerous mechanisms, not all of which are related to prevention of epithelial colonisation.

In previous studies, EIEC infection potentiated the secretory response of epithelial cells to the neuropeptide galanin. This would be expected to contribute to an infection associated increase in fluid and electrolyte secretion in vivo. Pretreatment with ST/LA blocked the ability of EIEC to potentiate secretion evoked by galanin (fig 7). Again, simultaneous exposure to EIEC and probiotics or addition of probiotics after EIEC failed to reverse the potentiated secretion (fig 7), independent of the size of the probiotic inoculum. These findings correlate to some degree to the results of adhesion and invasion experiments, although reduced adhesion evoked by simultaneous addition of probiotics and EIEC, especially at higher ST/LA MOIs, is not sufficient to prevent pathogen evoked hypersecretion. On the other hand, ST/LA spent medium was able to substantially prevent EIEC induced hypersecretory responses to galanin. As before, our data underscore the fact that both live probiotics and their secreted products can impact epithelial responses to pathogens but only the former can exert the full spectrum of preventative effects.

**Pretreatment with probiotics prevents EGF receptor inactivation induced by EIEC infection**

EIEC infection can prevent activation and/or increased degradation of the EGFR. Given the critical role of EGF and the EGFR in many aspects of gastrointestinal physiology and epithelial repair, we hypothesised that the beneficial effect of probiotics might extend to their ability to restore EGFR signalling in epithelial cells infected with EIEC. In fact, when cells were pretreated with probiotics, infected with EIEC, then

mitogenesis protein kinases are downstream effectors of the EGFr. Both EIEC and live probiotics induced early phosphorylation of the ERK 1,2 isoform of these kinases (fig 9). Antibiotic killed (fig 9) or heat inactivated (not shown) ST/LA alone were unable to activate ERK1/2. We also tested whether ERK 1 and 2 were activated under the various conditions studied following EGF stimulation. Pretreatment with live probiotics reversed the inhibition of ERK 1 and 2 activation induced by EIEC infection in a significant fashion (fig 9). There was no significant change in total ERK levels under any condition. EIEC failed to reverse the effects of EIEC infection on EGF induction=50:1) EIEC, or ST/LA followed by EIEC. Both living and antibiotic killed (†) ST and LA were tested in these experiments. Cells were harvested at 12 hours after infection. Whole cell lysates were immunoprecipitated with specific antibodies against occludin (A) or ZO-1 (B), then blotted with the same antibody or with an antiphosphoserine (A) or antiphosphotyrosine (B) antibody. The upper panels are representative blots whereas the lower panels show means (SEM) for densitometric analyses, n=6. **p<0.01; ***p<0.001 compared with uninfected controls (by ANOVA).

There was no significant change in total ERK levels under any condition. Antibiotic killed (fig 9) or heat inactivated (not shown) probiotics failed to reverse the effects of EIEC infection on EGF induced ERK1/2 phosphorylation (fig 9). These data further corroborate that probiotics likely have myriad protective effects in the intestinal epithelium.
DISCUSSION

The role of commensal and probiotic bacteria in the physiology of the gastrointestinal tract is incompletely understood. In particular, the mechanisms underlying the benefits derived from biotherapy with probiotics have not been sufficiently elucidated, with available data largely fragmentary and/or anecdotal. It is known that stimulation by commensal bacterial antigens is crucial for the normal development of the mucosal immune system and maintenance of tolerance. Moreover, probiotics have been shown to attenuate or abolish tumour necrosis factor α stimulated interleukin 8 production in intestinal epithelial cells. The studies described here provide additional evidence that, by diverse mechanisms, living probiotics are able to prevent or counteract the full spectrum of epithelial dysfunction induced by an enteroinvasive pathogen. In addition, probiotics alone, in the absence of EIEC infection, had effects that are arguably beneficial. Thus addition of live probiotics to naïve epithelial monolayers resulted in a progressive increase in their TER and an accompanying decrease in their permeability to a low molecular weight tracer.

Our findings demonstrate the ability of live probiotic bacteria to interfere with enteric pathogens through diverse mechanisms. Our data concur with recent work from other laboratories showing an important, but not exclusive, role for probiotic induced interruption of the early interactions of pathogens and host cells. Mack et al showed that part of the beneficial effect of L. plantarum and L. rhamnosus was mediated by induction of mucin genes in intestinal epithelial cells, thus preventing adherence of enteropathogenic E. coli. We do not know yet if S. thermophilus or L. acidophilus have similar effects in our models. However, only pre-treatment with probiotics prevented invasion of EIEC into epithelial cells and some, but not all, aspects of epithelial dysfunction associated with invasion, whereas simultaneous exposure to both probiotic and pathogenic bacteria had lesser preventative effects, especially at equivalent MOIs.

In our study, probiotic exposure following EIEC infection of epithelial monolayers had essentially no ability to prevent colonisation and invasion, or functional sequela. Our findings are mirrored in the reported need to administer large doses of

**Figure 7** Pretreatment with probiotics prevents galanin stimulated chloride secretory responses to enteroinvasive Escherichia coli (EIEC) infected HT29/cl.19A cell monolayers. HT29/cl.19A cell monolayers were exposed to medium alone, Streptococcus thermophilus and Lactobacillus acidophilus (ST/LA) alone, EIEC alone, ST/LA followed by EIEC, ST/LA alone, and EIEC simultaneously (ST/LA/EIEC), or EIEC followed by ST/LA (EIEC + ST/LA), or spent medium (SM) from ST and LA cultures with or without EIEC. Preparations of living or antibiotic killed (**) ST/LA were used. Monolayers were mounted in Ussing chambers at the times indicated and chloride secretory responses to galanin (100 nM) assessed as maximal increases in short circuit current (ΔIsc). *p<0.05, **p<0.001 compared with uninfected controls (by ANOVA).

**Figure 8** Pretreatment with probiotics prevents epidermal growth factor receptor (EGF) inactivation by enteroinvasive Escherichia coli (EIEC). HT29/cl.19A cell monolayers were exposed to medium, Streptococcus thermophilus and Lactobacillus acidophilus (ST/LA), EIEC, or ST/LA followed by EIEC. Both living and antibiotic killed (**) ST and LA were tested in these experiments. Before harvest at three hours after infection, cells were treated with EGF (50 nM, two minutes) or medium alone. After lysis and immunoprecipitation with anti-EGFr, proteins were electrophoresed and blotted with the same antibody or with anti-phosphorytase. The top panel shows representative blots whereas the bottom panel shows means (SEM) for densitometric analyses, n=6. ***p<0.001 compared with uninfected cells treated with EGF (by ANOVA) (n=4, means [SEM]).

**Figure 9** Effect of probiotics and enteroinvasive Escherichia coli (EIEC) on basal and epidermal growth factor (EGF) stimulated ERK 1 and 2 activation. HT29/cl.19A cell monolayers were exposed to medium, Streptococcus thermophilus and Lactobacillus acidophilus (ST/LA), EIEC, or ST/LA followed by EIEC. Both living and antibiotic killed (**) ST and LA were tested in these experiments. ERK 1 and 2 were also activated under the various conditions studied following EGF stimulation. The top panel shows two representative blots whereas the bottom panel shows means (SEM) for densitometric analyses. ***p<0.001 compared with uninfected cells (by ANOVA, n=6).
probiotics in vivo when attempting to control or attenuate ongoing gastrointestinal infections or inflammation. Specifically, Madsen et al showed that the use of a single probiotic strain alone was beneficial in reducing disease in IL-10 deficient mice only at high densities. Moreover, work in our laboratory suggests that different probiotics produce differing levels of bactericidal proteins with various degrees of efficacy against enteric pathogens, as well as autoinducers that can condition the formation of complex biofilms above the epithelial surface, conceivably thus modulating mucosal responses to the luminal environment (Resta-Lenert et al, unpublished observations). These findings emphasize the importance of investigating a diversity of host-microorganism interactions when profiling probiotics. Probiotics which display different characteristic phenotypes may be valuable as therapeutic tools under different pathophysiological conditions.

While either pretreatment or simultaneous inoculation (at appropriate MOIs) with live probiotics could limit EIEC invasion and TER alterations in epithelial cells, only pretreatment (at appropriate MOIs) with live probiotics could limit EIEC invasion and TER alterations in epithelial cells, only pretreatment

...respond very rapidly to invasive pathogenic bacteria with production of reactive oxygen species and nitric oxide as well as altered chloride secretion, indicating that both bacterial killing and "flushing out" may be first line defence mechanisms against the threat of invasion of the gastrointestinal mucosa. In this regard, it is perhaps fortuitous that probiotics, as administered clinically after infection has begun, might be unlikely to inhibit these putative beneficial adaptive responses to an infectious threat.

By preventing invasion and extensive colonization, probiotics considerably reduce the infective load and thus the oxidative stress that is in part responsible for the acute mucosal inflammation induced by enteric pathogens. Inhibition of oxidative stress at the site of mucosal infection might prevent EGF inactivation as observed as a consequence of acute in vitro infection with EIEC or rotavirus. It is well known that EGF and activation of the EGFR promote epithelial restitution after injury in several gastrointestinal pathological conditions and that EGF therapy produces improvement in colitis and gastric ulcers in both in vivo and in vitro models. EGF also regulates cell motility, proliferation, and maintaining the epithelial barrier function and transport properties of human intestinal epithelial cells: role of INOS and COX-2 expression. Gastroenterology 2002;122:1070-87.

We thank Ms Glenda Wheeler for secretarial assistance, and Dr Josh Tierer for supplying the EIEC strain used in this work. These studies were supported by NIH grant DK53108 (Unit 5), a grant from the Crohn's and Colitis foundation of America to KEB, and an NIH supplemental award to SRL. A preliminary account of this work was presented at annual meetings of the American Gastroenterological Association (2000, 2001) and at the "Gastrointestinal response to injury" meeting, Quebec, Canada (2001), and has been published in abstract form (Gastroenterology 2000;118:4325; Gastroenterology 2001;120:3801).
