Epithelial cells disseminate into the bone marrow of colorectal adenoma patients

Although the skeleton is not a preferred site of overt metastasis in colorectal cancer, demonstration of tumour cells in bone marrow has to be seen as evidence of the general disseminative capability of an individual tumour. Other observations such as involuntary transmission of tumour by organ grafts directly supports the notion that very few quiescent cells lodging at improbable sites, such as the kidney or heart, suffice to generate de novo metastatic disease in the organ recipient. The TNM classification recommends mention of the presence of disseminated tumour cells as a facultative factor for metastasis (M0 (ie) or M0 (mol+)) according to the immunological or molecular detection technique.

However, the results of the one and only meta-analysis available to date show that the prognostic impact of epithelial cells in the bone marrow of colorectal cancer patients has to be substantiated by further studies under standardised conditions. To further investigate this question, bilateral crest aspiration is performed routinely in our institution for neoplastic diseases. From September 1997 until July 2000, we investigated 233 patients undergoing colorectal surgery for neoplastic diseases. In a previous study, we examined the clonality of disseminated tumour cells in the bone marrow of 51 colorectal cancer patients by determining the mutational pattern in codons 12 and 13 of the K-ras gene. Our results demonstrated that, at least for K-ras mutations, disseminated epithelial cells are not always clonal with the primary tumour. The type of mutations suggested also that cell dissemination might be an early event in the development of colorectal neoplasms as most bone marrow K-ras mutations were found in codon 13, a codon barely mutated in invasive colorectal cancer but frequently mutated in aberrant crypt foci.

Obviously, epithelial cells can already disseminate in the polyp stage, in particular when so-called intraepithelial neoplasia is diagnosed. Indeed, dissemination of epithelial cells into the bone marrow in a stage defined as non-cancerous questions the carcinomatous nature of these cells, and in particular their micrometastatic nature. In contrast, should these cells be cancer cells—which we cannot exclude on the basis of our previous and present observations—then the benign nature of intraepithelial neoplasia should in turn be challenged.

In a previous study, we examined the clonality of disseminated tumour cells in the bone marrow of 51 colorectal cancer patients by determining the mutational pattern in codons 12 and 13 of the K-ras gene. Our results demonstrated that, at least for K-ras mutations, disseminated epithelial cells are not always clonal with the primary tumour. The type of mutations suggested also that cell dissemination might be an early event in the development of colorectal neoplasms as most bone marrow K-ras mutations were found in codon 13, a codon barely mutated in invasive colorectal cancer but frequently mutated in aberrant crypt foci.

We would be delighted to receive feedback from other researchers that would help us to interpret the present observation.

DNA from blood and from frozen JNA tissue carrier who underwent restorative proctocolectomy, and heteroduplex analysis on agarose mini gels, and restriction enzyme analysis, using these techniques we detected a frameshift mutation, c.3927-3931delAAAAGA, in both blood and JNA tissue. This mutation introduces a stop codon (pGlu1309fsX1312) in the APC gene region between the first and second 20 amino acid β-catenin binding repeats. Another frameshift APC mutation, consisting in a 5 bp deletion, c.3183-3187delACAAA, that introduces a stop codon (p.Lys1061fsX1062) in the region encoding the first 20 amino acid β-catenin binding repeat, was detected only in JNA DNA. Using restriction enzyme analysis, we ruled out the presence of the JNA associated activating mutations at codons 32 and 34 in exon 3 of the β-catenin gene. These results were confirmed in duplicate experiments. Due to lack of tumour sections, we were unable to perform laser capture microdissection to separate the vascular and stromal components of the tumour. However, the somatic mutation is expected to have been present in fibroblasts because of the clear stromal predominance in the JNA tissue analysed.

In the study by Abraham et al, activating β-catenin mutations were found in 12 of 16 sporadic JNAs analysed. The APC sequence corresponding to the mutation cluster region (MCR) of sporadic colorectal cancer was investigated in the four JNAs without β-catenin mutations but no mutations were detected. Guerri et al analysed 11 sporadic JNAs from nine patients for mutations in the MCR of the APC gene and for loss of heterozygosity (LOH) at the APC locus. No APC mutations were detected and none of the informative cases were LOH positive. Ferouz et al found no germline APC mutations in a series of nine JNA patients. Thus there was no direct evidence involving the APC gene in JNA, although this rare tumour is reported to occur 25 times more frequently in FAP affected adolescents than in an age matched population.

This study documents for the first time the association between a somatic and a germline APC mutation in an FAP related JNA. Because of the stromal predominance in the tumour analysed (fig 1), the somatic mutation must have been present in the fibroblasts (that is, in the same cell type where nuclear accumulation of β-catenin, indicative of activation of the Wnt pathway, was previously demonstrated). We cannot exclude the presence or absence of the mutation in the vascular component. Our findings agree with the well known evidence of double hit APC inactivation in FAP associated fibroblastic tumours. Thus FAP associated JNA should be considered a sex dependent extraintestinal FAP manifestation.

Evaluation of vascular signal in pancreatic ductal carcinoma using contrast enhanced ultrasonography: effect of systemic chemotherapy

Evaluation of the effect of chemotherapy for pancreatic ductal cancer (PC) is generally conducted based on changes in tumour diameter using imaging modalities; however, exact measurement is often difficult because of local inflammation, fibrotic change, and desmoplastic reaction to treatment, leading to an unreliable evaluation. PC is considered a hypovascular tumour. However, recently developed high-sensitive ultrasonic equipment has enabled the detection of vascular signals in PC; vascular signals were detected in 20–67% of cases. We focused on changes in tumour vascularity of PC associated with chemotherapy, and attempted to apply it to evaluation of the effect of treatment and usefulness in relation to prognosis. In this study, we assessed vascular images of the tumour based on the Doppler signal using contrast enhanced ultrasonography (CEUS).

Thirty one histopathologically confirmed consecutive patients with PC who had distant metastases were included in the study. Informed consent was obtained from all patients and the study was approved by the ethics committee. The tumour was located in the head of the pancreas in 16 patients and in the body or tail in 15. All patients were treated with a combination of S-1, an oral fluorinated pyrimidine derivative, and gemcitabine. Chemotherapy was performed every three weeks as one cycle. CEUS was performed before and after one and two cycles of treatment. In this study, treatment effect after two cycles of chemotherapy was examined. In this study, treatment effect after two cycles of chemotherapy was evaluated based on changes in tumour diameter, fibrotic change, and desmoplastic reaction to treatment leading to an unreliable evaluation. However, newly developed high-sensitive ultrasonic equipment has enabled the detection of vascular signals in PC; vascular signals were detected in 20–67% of cases. We focused on changes in tumour vascularity of PC associated with chemotherapy, and attempted to apply it to evaluation of the effect of treatment and usefulness in relation to prognosis. In this study, we assessed vascular images of the tumour based on the Doppler signal using contrast enhanced ultrasonography (CEUS).

The effect of treatment (PR, SD, PD) was as follows: partial response (PR) in five patients (16%), stable disease (SD) in 17 patients (55%), and progressive disease (PD) in nine patients (29%). A significant decrease in the v signal score was observed in PR compared with PD before and after one cycle of treatment (p = 0.0099 and p = 0.0017, respectively). After two cycles of treatment, the decrease was conspicuous in PR (p = 0.0022 and p = 0.0021, respectively) whereas in PD a significant increase in the v signal score was observed compared with SD (p = 0.0160). In univariate analysis, the increase in v signal (before the second cycle) was a significant prognostic factor (p = 0.0150). Median survival time of patients in the non-increased v signal group (n = 12) after two cycles of treatment was 382 days (71–484) and for those in the increased group (n = 9), 176 days (68–257). Thus, the patients in the increased group had a significantly shorter survival than those in the non-increased group (p = 0.0094) (fig 1).

In conclusion, analysis of tumour vascularity by CEUS evaluated the effect of treatment much earlier than dynamic CT, and predicted prognosis in patients with PC.

Ferroportin disease due to the A77D mutation in Australia

Ferroportin disease or type 4 haemochromatosis is an autosomal dominant iron overload disorder caused by mutations in the iron exporter ferroportin. Numerous mutations in ferroportin (SLC40A1) have been identified (see review by Pietrangeli). The A77D mutation of ferroportin has thus far only been reported in Italy. We report the first A77D mutation of ferroportin which resulted in hepatic iron overload in an Australian family. The study was approved by and performed in accordance with the ethical standards of the Queensland Institute of Medical Research Human Ethics Committee and the Helsinki Declaration of 1975, as revised in 1983. Informed and written consent was obtained from the patient and family members.

The subject, a 45 year old Caucasian male, presented with complaints of lethargy and malaise. He had no risk factors for viral hepatitis, consumed minimal alcohol (20 g/week), and was married with two children. Physical examination was normal, including a normal body mass index.

Initial investigations revealed a haemoglobin level of 12.2 g/dl, white blood count of 3.8×10^3, and platelet count of 135×10^3. Serum ferritin concentration was 3500 μg/l and a transferrin saturation (TS) of 29%. Molecular analysis did not reveal the presence of the C282Y, H63D, or S65C mutations of HFE.

Liver biopsy was performed and revealed significant Kupffer cell iron loading with minimal staining in hepatocytes, as detected by Perls' Prussian blue staining. No fibrosis was detected. Hepatic iron concentration was 96 μmol/g dry weight (normal 5–35) with a hepatic iron index of 2.1 (normal <1.1). No other secondary cause for iron loading (for example, thalassemia, porphyria cutanea tarda, or chronic liver disease) was detected.

Liver histology and biochemistry were suggestive of ferroportin disease. The entire coding region and splice sites of the ferroportin gene from the proband were polymerase chain reaction amplified and sequenced, as previously described. Other family members were subsequently evaluated.

The presence of a cysteine to adenine change at nucleotide 230 of ferroportin, which results in mutation of an alanine to aspartic acid at amino acid 77 (A77D), was identified in the proband. Subsequently, this change was also identified in the proband’s father, sister, and daughter (fig 1). This is the same mutation which was identified in Italy by Montosi and colleagues. There is no known ancestral link between the family reported here and that in Italy. Thus it is likely that the A77D mutation has occurred in two populations separately, as appears to be the case with the V162del mutation. This has so far been reported in five geographic locations.

As knowledge about ferroportin disease is uncommon in the community, unlike HFE associated haemochromatosis, it is possible that some cases of this disorder are not recognised and thus remain undiagnosed. This particular case was not diagnosed until report also suggests that some cases of ferroportin disease may go undiagnosed. Ferroportin disease should thus be considered when a patient presents with a high serum ferritin, even when transferrin saturation and HFE genotype are normal.

HHV-8 positive, HIV negative disseminated Kaposi’s sarcoma complicating steroid dependent ulcerative colitis: a successfully treated case

We present the case of a 49 year old man who had suffered histologically confirmed ulcerative colitis (UC) since 1998. He had been asymptomatic for four years when in August 2002 an acute relapse developed. Colonoscopy and histology of a superficial bowel specimen showed clear signs of active UC with no signs of malignancy. Despite adequate therapy he failed to improve and was referred for restorative proctocolectomy because of steroid dependency and end stage colitis. By the time of his referral, violaceous reddish-brown nodules had developed on his extremities. Skin biopsy showed spindle cells and vascular slits. Histological diagnosis was Kaposi’s sarcoma (KS) of the skin. He underwent a restorative proctocolectomy with ileostomy in March 2003. The pathological examination of the colon showed features of UC and surprisingly, characteristic signs of KS also. Human immunodeficiency virus (HIV) tests were negative. Human herpesvirus-8 (HHV-8) DNA was detected in native samples from affected skin but not in peripheral blood or the large intestine. The patient recovered rapidly after operation. Steroid therapy was gradually withdrawn. Cutaneous lesions regressed completely with hyperpigmentation, and no new lesions were observed, despite receiving no treatment (fig 1).

There are four clinical variants of KS: classic, endemic, acquired immunodeficiency syndrome (AIDS) associated, and iatrogenic. Excessive use of immunosuppressive drugs in the second part of the 20th century has been associated with a higher prevalence of iatrogenic KS. Start of the disease, after administration of the triggering drug in previously reported studies, ranged from less than one month to more than 20 years. The dose of steroid ranged from 5 to 125 mg/day. There was no evident correlation between the development of KS and dose or duration of steroid therapy. Our patient had been treated with 12–125 mg methylprednisolone daily for about four months when his skin lesions appeared. Reduction or discontinuation of immunosuppressive drugs often leads to considerable improvement in KS lesions. In accordance with these data, after withdrawal of steroid therapy the skin symptoms of our patient regressed spontaneously. Visceral KS is quite frequent in AIDS patients and can affect virtually all viscera, but colonic KS is rare. These patients are often asymptomatic or have asymptomatic symptoms. As KS affects the submucosa more often, superficial bowel biopsies frequently miss it, as happened in our case. A link between HHV-8, a gamma herpesvirus, and KS was first reported more than 10 years ago. The virus was found in more than 90% of KS samples from HIV seropositive patients but has low prevalence in healthy controls. HHV-8 DNA persists in endothelial cells and spindle cells of KS. According to the literature, the HHV-8 virus alone is not sufficient to form KS but it may be an important cofactor in the development of the disease. In our case, we detected HHV-8 genome in native samples from skin lesions but failed to do so in paraffin embedded colonic samples. The occurrence of colonic KS and UC together is rare. We found eight similar cases in the English literature (table 1).

Our patient was the fourth who was HIV negative and developed KS in association with UC. To our knowledge he was the first proven HHV-8 positive case who developed disseminated KS during immunosuppressive treatment for UC. Our treatment policy was successful. The patient, in spite of his poor condition, tolerated the surgical therapy well. After cessation of his steroid therapy KS regressed spontaneously. He remains well 35 months after surgery.

The list of authors for the Editor’s quiz: GI snapshot on page 672 of the May issue was published in the incorrect order (CJM de Groot et al). The correct author list is as follows: CJM de Groot, GM van Goor, MF Stolk, G Kazemier, PE Zondervan, HJ Metselaar, IR Wanless, and HLA Janssen.

doi: 10.1136/gut.2004.045252

EDITOR’S QUIZ: GI SNAPSHOT

Answer

From question on page 927

A 100 mm segment of the proximal jejunum had an irregular outline, with areas of constriction due to scarring. Histology (fig 2) showed fibrosis of the subserosa, and interruption and replacement of the muscularis propria by fibrosis. The submucosa and epithelium were normal.

The diagnosis was seat belt injury.

Two proposed mechanisms explain the occurrence of small bowel obstruction after blunt abdominal injury: direct and indirect. The direct theory postulates that visera get compressed between the abdominal wall and spinal column under the shearing force of the fastened seat belt. In the healing process, fibrosis causes strictures that may result in partial or complete obstruction.

In the indirect mechanism, visera suffer from ischaemia secondary to mesenteric injury, with involvement of the superior and inferior mesenteric arteries. As Miss M’s mesenteric structures were normal on laparotomy, the scarring she sustained seems to have been the result of direct trauma to the gut. The duodenum and jejunum are particularly vulnerable in the seat belt syndrome because of their proximity to the vertebral column, as well as their relation to the fastened seat belt.

Figure 2 Histology of the proximal jejunum. The mucosa and submucosa are normal, whereas there is interruption of the muscularis propria, with fibrous scarring (between the arrows). Van Gieson stain, original magnification ×100.

The affected segment was excised and this patient was discharged, totally recovered, nine days after surgery.
