SUMMARY
Hepatic steatosis is a common histological feature of chronic hepatitis C. Various factors are associated with hepatic steatosis, including obesity, high alcohol consumption, diabetes type II, and hyperlipidaemia. These factors may contribute to steatosis in patients with chronic hepatitis C. In humans, hepatitis C virus (HCV) genotype 3 is more commonly associated with steatosis. In vitro studies and the transgenic mouse model have suggested that the HCV core protein (genotype 1) can induce lipid accumulation within hepatocytes.

However, what is the relevance of steatosis in chronic hepatitis C? It seems that in certain populations, steatosis may be associated with fibrosis progression and this may be genotype specific. The mechanisms underlying this association are unknown; neither is it clear whether this holds true for all patients or only a subgroup. Indeed, after antiviral treatment, virus related steatosis disappears whereas the host associated steatosis remains unaffected.

This review describes and discusses the basic and clinical aspects of the relationship between steatosis and progression of fibrosis, and response to treatment in patients with chronic hepatitis C.

INTRODUCTION
HCV is a major cause of chronic liver disease with about 170 million people infected worldwide. The severity of disease varies widely from asymptomatic chronic infection to cirrhosis and hepatocellular carcinoma.

Non-alcoholic fatty liver disease (NAFLD) represents a spectrum from simple steatosis at one end to severe inflammation with extensive fibrosis or cirrhosis at the other. Hepatic steatosis without inflammation is thought to have a good prognosis but non-alcoholic steatohepatitis (NASH) can progress to cirrhosis in a significant proportion of cases.

Hepatic steatosis is also a common histological feature of chronic hepatitis C but may be independently associated with obesity, high alcohol consumption, type II diabetes, and hyperlipidaemia and, when these occur, may contribute to steatosis in patients with chronic hepatitis C. In this review we will focus on the relevance of steatosis in patients with chronic hepatitis C with respect to disease outcome.

FREQUENCY OF STEATOSIS IN CHRONIC HEPATITIS C PATIENTS IN COMPARISON WITH THE GENERAL POPULATION
Hepatic steatosis can develop secondary to obesity, diabetes mellitus, alcohol abuse, protein malnutrition, total parenteral nutrition, acute starvation, drug therapy, carbohydrate overload, and chronic hepatitis C infection. An excellent review of lipid metabolism has been published elsewhere (fig 1). Estimates based on imaging and autopsy studies suggest that approximately 20–30% of adults in the USA and other Western countries have excess fat accumulation in the liver; approximately 10% of these individuals (that is, 2–3% of adults) are estimated to have NASH. Wanless and Lentz found steatosis in 70% of obese and 35% of lean patients in a consecutive autopsy study. The prevalence of steatosis in patients with abnormal liver tests (in which known causes of liver disease have been excluded) is 64%; of these 50% had steatosis and 50% had steatohepatitis.

In chronic hepatitis C patients, the prevalence of steatosis ranges from 40% to 86% (mean –55%) (table 1). The majority of patients with steatosis (78%) have mild steatosis affecting less than 30% of hepatocytes. Thus steatosis occurs more frequently in patients with chronic hepatitis C (55%) than in the general population (20–30%) of adults in the Western world.

FACTORS ASSOCIATED WITH STEATOSIS IN CHRONIC HEPATITIS C PATIENTS
Patients with HCV infection may have coexisting obesity, diabetes, alcohol abuse, etc., which contribute to the development of fatty liver (box 1). In many studies a link between steatosis and
a high body mass index (BMI) has been reported (table 2). Adinolfi et al reported that overall, steatosis was not significantly associated with BMI, but when analysis was done by single genotype, a significant association was shown between high visceral fat distribution and grade of steatosis in HCV genotype 1 patients (but not in genotype 3). This led to the idea that in patients with HCV infection there is a "metabolic fat" (especially in patients with HCV genotype 1) and a "viral fat" (especially in patients with genotype 3). Epidemiological studies have suggested a link between type 2 diabetes and chronic HCV infection. However, the presence of confounding factors such as obesity, aging, or cirrhosis precludes the establishment of a definite relationship between these two conditions.

STEAUTOSIS, HCV GENOTYPE 3, AND VIRAL REPLICATION

Several studies have observed a significant association between HCV genotype 3 infection and the presence of steatosis (table 1). In our study, including 290 chronic hepatitis C patients, steatosis, in multivariate analysis, was associated with HCV genotype 3 infection, higher BMI, and a higher grade of necroinflammation. Thus steatosis is more frequent in HCV genotype 3 than in HCV genotype 1 infected patients. Steatosis is present in 73% of patients infected with genotype 3 and in 50% of patients infected with genotypes other than 3 (table 1). The mechanisms underlying this genotype specific steatosis are unknown. We have recently shown that HCV genotype 3 is associated with higher quasispecies heterogeneity than genotype 1. Serum levels of apolipoprotein B and cholesterol are reduced in patients in whom steatosis responds to antiviral therapy. Thus the disappearance of steatosis correlates with normalisation of apolipoprotein B and cholesterol levels. Hypocholesterololemia in patients with chronic hepatitis C (especially genotype 3) has been reported by others. However, other studies have not confirmed this.

A significant correlation was observed between steatosis and high titres of intrahepatic negative strand HCV RNA in patients infected with HCV genotype 3, indicating that steatosis may be secondary to a viral cytopathic effect. In two studies in patients with HCV genotype 3, an association between grade of steatosis and serum HCV RNA levels was observed. However, other studies have not confirmed this.

that the core proteins from both genotypes 1b and 3a share the capability of inducing accumulation of triglycerides in Huh-7 hepatoma cells, although genotype 3a is much more efficient. These results raise the issue of which factors, other than the HCV core protein, may induce steatosis observed in humans. In particular, the role of other viral proteins should be properly investigated.

**DOES STEATOSIS AFFECT THE PROGRESSION OF THE DISEASE?**

**Limitations of published studies**

Published data on the influence of steatosis in chronic hepatitis C have several limitations. Firstly, only limited studies are available, almost all being cross sectional or retrospective. Histological criteria for fatty liver disease may be different and the populations studied may have different risk factors for steatosis. For example, in a study from the USA, mean BMI was 28.5 kg/m² and 32% of patients were obese, whereas in our study (France), mean BMI was 24 kg/m² and only 8% of patients were obese. Moreover, the HCV genotype distribution differs from region to region. For example, genotype 3 is more frequent in Europe (24%) than in the USA (14%).

**Experimental models: steatosis and fibrosis development**

In animal models, such as the leptin deficient ob/ob mouse or the leptin receptor deficient mouse (db/db) and rat (fa/fa), there is very marked hepatic steatosis but little steatohepatitis or fibrosis. Development of steatohepatitis in these models depends on additional factors, such as endotoxin exposure, acute liver injury (for example, ischaemia-reperfusion), alcohol, excess dietary polyunsaturated fatty acids, or aging. A unifying hypothesis envisages that all causes capable

---

**Figure 2** Pathogenesis of liver fibrosis in chronic hepatitis C. Proposed mechanisms leading to steatosis and fibrosis in hepatitis C virus (HCV) infection. Steatosis may be caused directly by HCV core protein expression (with or without the cooperation of other viral proteins) but other mechanisms are likely, such as the hyperglycaemic/hyperinsulinaemic state, the hallmark of insulin resistance (where HCV may play an additional direct role through activation of cytokines), and production of reactive oxygen species (ROS) (again, possibly induced by HCV and by insulin resistance). Furthermore, steatosis renders hepatocytes more insulin resistant and, on the other hand, provides the fuel for amplifying the production of ROS. Fatty accumulation, however, is not fibrogenic per se. The production of ROS may provide a pathogenetic link between steatosis and fibrosis. ROS induce cytokines formation by hepatocytes (tumour necrosis factor α (TNF-α), transforming growth factor β (TGF-β), interleukin 8 (IL-8), and FasLigand (FasL)). TGF-β activates collagen synthesis by stellate cells while IL-8 is a potent chemoattractant for human neutrophils. ROS trigger lipid peroxidation, which releases malondialdehyde (MDA) and 4-hydroxynonenal (HNE). MDA and HNE also increase collagen synthesis by stellate cells while HNE is a potent chemoattractant for human neutrophils. Additional fibrogenetic stimuli are represented by the fibrogenic inflammatory cytokines (released as part of both innate and adaptive immune responses to HCV infection and antigen expression) and by the direct profibrogenic effect of hyperinsulinaemia.
of changing the redox equilibrium of the hepatocyte may result in liver inflammation and fibrogenesis activation. For example, ROS may promote hepatic stellate cell activation and collagen fibre deposition. Lipid peroxidation products, such as 4-hydroxy-2,3-nonenal, may elicit activation and nuclear translocation of c-Jun N-terminal kinases, upregulate c-Jun and increase AP-1 binding, all of which may lead to procollagen type 1 overexpression. Furthermore, these phenomena are efficiently prevented by antioxidants.

**Direct involvement of HCV in the development of insulin resistance**

A prominent mechanism linking steatosis and fibrogenesis is insulin resistance. The molecular cause of insulin resistance, a major factor in the pathogenesis of type 2 diabetes, is unknown. Several papers have suggested an association between chronic hepatitis C and type 2 diabetes. This is relevant as prolonged hyperglycaemia results in several metabolic changes that are of interest in liver fibrogenesis and recent studies show a close correlation between the degree of insulin resistance and extent of fibrosis.

Recently, it was shown that glucose tolerance was impaired in a mouse model transgenic for the HCV core gene, with plasma glucose levels being higher at all time points, including in the fasting state, although the difference was not statistically significant. Transgenic mice exhibited marked insulin resistance, as revealed by the insulin tolerance test, as well as significantly higher basal serum insulin levels. Feeding with a high fat diet led to the development of overt diabetes in transgenic mice but not in control mice. Moreover, there were increased levels of tumour necrosis factor α (TNF-α) in the liver of HCV core gene transgenic mice. High levels of TNF-α have also been observed in human chronic hepatitis C patients. TNF-α has been shown to induce insulin resistance in experimental animals and cultured cells. Inhibition of tyrosine phosphorylation of insulin receptor substrate 1 and 2 may be one of the mechanisms by which a high level of TNF-α causes insulin resistance. Thus TNF-α was considered to be a predominant cause of insulin resistance in transgenic mice. Administration of an anti-TNF-α antibody restores insulin sensitivity. These results provide direct experimental evidence for the contribution of HCV in the development of insulin resistance. There are experimental arguments for a direct role of insulin in fibrosis progression in HCV infection.

Firstly, insulin receptors were identified on hepatic stellate cells isolated from liver sections from patients with chronic HCV infection. Secondly, in hepatic stellate cells, connective tissue growth factor mRNA and protein were significantly increased following incubation with insulin.

Diabetes per se may lead to increased production of ROS, and secondary upregulation of antioxidant genes, glycosylation of low density lipoprotein and other proteins, as well as the formation of advanced glycation end products (AGE).

Expression of the AGE specific receptor (RAGE) in the liver is restricted to stellate cells, and is upregulated at the time of activation and transition to the myofibroblasts phenotype. In genetically obese rodents, characterised by severe steatosis, insulin resistance is promoted by increased activity of IkappaB kinase-β, the activator of nuclear factor κB (NFκB). The latter is a transcription factor that plays a key role in expression of several proinflammation genes. Activation of NFκB may occur via oxidative stress mediated signalling involving the p38 mitogen activated protein kinase (MAPK). The link between insulin resistance and steatosis is complex, and the exact sequence of events is unclear, although several hypotheses have been made. Again, a potential link between severity of steatosis and fibrosis may be secondary to increased formation of reactive oxygen species by stecytic hepatocytes (fig 2).

**Human studies: steatosis and fibrosis progression**

Factors influencing fibrosis progression in chronic hepatitis C are poorly understood (box 2). There is some controversy with regard to the influence of steatosis on the progression of fibrosis. Among 14 studies, 10 found an association between the presence of steatosis and a higher degree of fibrosis (table 3). However, in most of these studies this association was of low statistical significance. Furthermore, the histological scores used were different, multivariate analysis was not always performed, and the study populations were different regarding risk factors for steatosis. Thus one possible explanation accounting for the discrepancies is that steatosis may be a cofactor of accelerated fibrosis progression as a function of its pathogenesis (that is, viral v metabolic).

The fact that obesity has been related to the risk of cirrhosis is an argument for a role of metabolic steatosis in the progression of fibrosis. In several studies, among alcoholics and patients with HCV infection, obesity favoured fibrosis. Fibrosis can indeed develop in overweight patients that are.

## Box 2 Factors associated with more rapid fibrosis progression in chronic hepatitis C

- Associated
  - Male sex
  - Duration of infection
  - Age at infection (older)
  - Long term excessive alcohol consumption
  - Long term immunosuppression (organ transplantation, bone marrow transplantation)
  - HCV coinfection
  - Overweight
  - High initial fibrosis stage
  - High initial necroinflammation grade
- Possibly associated
  - Steatosis
  - Insulin resistance
  - High HCV heterogeneity
  - HCV genotype 3
  - Cigarette consumption

### STEATOSIS IN CHRONIC HEPATITIS C

**Hepatitis C virus, insulin resistance, and fibrosis**

In one interesting study, Hui and colleagues observed that patients with chronic hepatitis C with mild fibrosis (stage 0 or 1) had higher levels of insulin, C peptide, and HOMA-IR (all p < 0.01) compared with matched healthy controls. In the 250 hepatitis C virus patients (fibrosis stages 0–4), independent predictors of HOMA-IR included higher BMI (p < 0.001), previous failed antiviral treatment (p < 0.001), portal inflammatory grade (p < 0.001), and genotype 3 infection (p = 0.01). Genotype 3 had significantly lower HOMA-IR than other genotypes (which were comparable when adjusted for the effects of the remaining independent predictors). HOMA-IR was an independent predictor for the degree of fibrosis (p < 0.001) and the rate of fibrosis progression (p = 0.03).

HCV may induce insulin resistance irrespective of the severity of liver disease, and this effect seems to be genotype specific. Furthermore, their findings support the hypothesis that insulin resistance may contribute to fibrosis progression in chronic HCV infection. Interestingly, insulin resistance may contribute to fibrosis progression in chronic HCV infection independent of the grade of steatosis. Surprisingly, in this study, HCV genotype 3 had significantly lower insulin resistance than other genotypes.

In another recent study, marked steatosis was associated with HCV genotype 3 infection and high BMI. Overweight patients had increased circulating insulin compared with lean patients. More advanced fibrosis was associated with obesity and insulin concentrations. Interestingly, in obese patients with chronic HCV infection, circulating insulin levels increased at an early stage of fibrosis (an argument for a causal role). We should remember that in patients with NAFLD, increasing insulin resistance is associated with more severe disease and diabetes is a risk factor for disease progression. Therefore, in overweight patients with HCV infection, increasing circulating insulin levels may be one factor responsible for the association between increasing BMI and fibrosis.

In a retrospective survey, high serum glucose was found to be associated with advanced fibrosis and higher fibrosis progression rate in chronic hepatitis C patients, and was independent of age at infection or duration of infection. The profibrogenic impact of glucose intolerance was higher than obesity. High serum glucose has also been independently associated with fibrosis in alcoholic liver disease.

### STEATOSIS AND NECROINFLAMMATION

Several studies found a link between necroinflammation and steatosis (table 3). Necroinflammatory activity in chronic hepatitis C may fluctuate over time. There are several mechanisms which may account for the relationship between steatosis and necroinflammation. In vitro studies have shown that the HCV core protein could lead to oxidative stress. Moreover, HCV is associated with increased production of cytokines that enhance inflammation and lead to increased lipid peroxidation. Furthermore, some patients may have NASH in addition to having chronic hepatitis C. Steatosis could be the consequence of more severe cell injury and necroinflammation rather than the direct cause of worsening fibrosis.

### HOW TO RECONCILE ALL OF THESE DATA?

Taking into account all of the published data, it seems that there is an association between steatosis and fibrosis. But does this mean that steatosis is the cause of fibrosis progression? Steatosis could be a marker of necroinflammation and therefore a marker of fibrosis progression as several studies found a significant association between necroinflammation and high stage of fibrosis. Steatosis could also be a marker of insulin resistance. In patients with HCV infection, insulin resistance may be one factor responsible for both steatosis in one way and increasing fibrosis in another. Interestingly, we reported recently the rate and risk of cirrhosis in 96 patients infected by HCV during the bone marrow transplantation period. At a median follow up of 15.7 years, 15 patients developed biopsy proven cirrhosis leading to a cumulative incidence of cirrhosis of 24% at 20 years. By multivariate analysis, HCV genotype 3 was associated with risk of cirrhosis.

### DOES TREATMENT IMPROVE STEATOSIS?

We initially reported a patient with HCV genotype 3 infection, recurrent hepatitis after liver transplantation, and massive steatosis, in whom steatosis disappeared when HCV replication was inhibited by treatment and recurred when replication relapsed after treatment withdrawal. This
observation was confirmed by other studies, thus supporting a cytopathic effect of HCV genotype 3. In the first study, Kumar and colleagues reported that in patients with HCV genotype 1 (n = 28) there was no change in steatosis after treatment, irrespectively of response; however in those infected with genotype 3 (n = 34), a sustained virological response (SVR) resulted in significantly reduced steatosis (p<0.001) but no change in steatosis among those without an SVR. In another study involving 1428 naive patients, the presence of steatosis was associated with a lower SVR (p<0.001) but in patients with an SVR, steatosis was most improved in those with HCV genotype 3. In genotype 3 responders, baseline low serum cholesterol was corrected by treatment (p<0.001). These results have been confirmed by others.21

Interestingly, in a retrospective analysis of 174 patients with chronic hepatitis C, obesity (and not steatosis) was a negative predictor of SVR.23 It could be that obesity causes steatosis and that each independently diminishes SVR. Obesity decreases interferon bioavailability and impairs the immune response to HCV. The mechanisms underlying the influence of steatosis on SVR remain to be determined. An intriguing aspect that arises from these studies is the fact that steatosis seems to negatively influence SVR, as suggested by earlier reports.21-27 This phenomenon seems to be limited to patients with chronic hepatitis C, obesity (and not steatosis) was a negative predictor of SVR. In another study involving 1428 naive patients, the presence of steatosis was associated with a lower SVR (p<0.001) but in patients with an SVR, steatosis was most improved in those with HCV genotype 3. In genotype 3 responders, baseline low serum cholesterol was corrected by treatment (p<0.001). These results have been confirmed by others.21

It is interesting to note that interferon α and insulin share some factors in signalling transduction, such as p38 MAPK; whether insulin resistance translates into a relative resistance to interferon α remains a matter of speculation.

CONCLUSION
The relationship between HCV and steatosis in terms of fibrosis and disease progression is unclear. HCV genotype 3 is clearly associated with steatosis (“viral steatosis”). It seems that in some patients, steatosis may be associated with fibrosis progression. The mechanisms underlying this association are unknown. The challenge for the clinician in care of patients with chronic hepatitis C infection and steatosis is to be able to differentiate between those with pure steatosis alone and a benign course from those with progressive disease (the same challenge in separating NASH from NAFLD).

There remain many unanswered questions and there is a need for large prospective studies on hepatitis C patients, using multivariate analysis, which take into account confounding factors for steatosis, insulin resistance, fibrosis, and response to treatment. A meta-analysis of individual patient data (the HCV MAID Study) is ongoing to investigate the relationship between steatosis, inflammation, and fibrosis in chronic hepatitis C. Moreover, we need to develop experimental models using different HCV genotypes in order to understand the mechanisms leading to steatosis.
