Monocyte chemotactic protein 1 and macrophage cyclooxygenase 2 expression in colonic adenoma

S Tanaka, A Tatsuguchi, S Futagami, K Gudis, K Wada, T Taki, M Yonezawa, K Nagata, S Fujimori, T Tsukui, T Kishida, C Sakamoto

Background and aims: Cyclooxygenase 2 (COX-2) expression in subepithelial macrophages of colorectal adenoma has been suggested as the first in a series of steps leading to colorectal tumorigenesis. We tested the hypothesis that chemokines released from human colorectal adenoma epithelium might be involved in COX-2 expression in macrophages of the lamina propria.

Methods: Endoscopic samples of sporadic colorectal adenomas were tested by enzyme linked immunosorbent assay for chemokines involved in macrophage chemotaxis. Localisation of adenoma macrophage chemotactic protein 1 (MCP-1) and COX-2 were determined by immunohistochemistry. The effects of MCP-1, in the presence or absence of celecoxib, on COX-2 expression, and prostaglandin (PG) E2 and vascular endothelial growth factor (VEGF) release, were examined in human macrophages isolated from peripheral blood.

Results: MCP-1 levels were markedly higher in adenoma with mild-moderate dysplasia (129.7 (19.9) pg/mg protein) and severe dysplasia (229.7 (35.4) pg/mg protein) than in normal colonic mucosa (55.8 (4.2) pg/mg protein). Other chemokine levels, macrophage inflammatory proteins (MIP)-1α and MIP-1β, and the chemokine regulated on activation of normal T cell expressed and secreted (RANTES) did not vary significantly between adenoma and normal mucosa. MCP-1 levels in both adenoma and normal colonic mucosa increased significantly three hours after tissue cultivation in vitro. MCP-1 immunoreactivity was restricted to the adenoma epithelium, with no reactivity seen in adjacent normal epithelial cells. MCP-1 stimulated COX-2 expression and PGE2 and VEGF release in human macrophages. Celecoxib, a selective COX-2 inhibitor, inhibited MCP-1-induced PGE2 and VEGF release in macrophages. Addition of exogenous PGE2 reversed this inhibitory effect on VEGF release, suggesting that MCP-1 in adenoma epithelial cells might be involved in COX-2 expression and subsequent macrophage activation.

Conclusions: MCP-1 in colorectal adenoma epithelial cells might be involved in macrophage migration and COX-2 expression, leading to the subsequent development of colonic adenoma.

Epidemiological studies have shown that subjects on a regimen of aspirin or other non-steroidal anti-inflammatory drugs (NSAIDs) known to inhibit cyclooxygenase (COX) activity have a reduced risk of developing colon cancer. In addition, recent clinical randomised trials have shown the therapeutic value of aspirin both in the prevention of colorectal cancer and its recurrence. Studies have also shown that NSAIDs decrease the size and number of polyps in patients with familial adenomatous polyposis (FAP). COX-2 has been found to be expressed not only in interstitial cells infiltrating human colorectal adenoma and cancer tissue but also in cancer cells themselves. However, recent studies have shown that at the onset of tumorigenesis in the colon, COX-2 expression is limited to macrophages localised just beneath epithelial cells of polyps in APC716 knockout mice, an animal model of human FAP, and in the subepithelium of mild dysplasia human adenoma. Also, COX-2 gene knock-out or administration of selective COX-2 inhibitors have been shown to decrease the number and size of intestinal polyps in APC716 mice. These data suggest that COX-2 expressed in macrophages plays a crucial role in adenoma growth and its progression to colon cancer. Recent studies also show intense vascularityisation in interstitial areas populated with COX-2 positive macrophages, suggesting a possible functional relationship between macrophage COX-2 expression and angiogenesis. However, the mechanisms through which macrophages infiltrate into the lamina propria at the epithelial border, and express COX-2, have yet to be determined in adenoma of the colon.

The high macrophage density in tumours of the colon is thought to be primarily maintained by recruitment of circulating monocytes. Most members of the –CC chemokine family, including macrophage chemotactic protein (MCP)-1, macrophage inflammatory proteins (MIP)-1α and MIP-1β, and the chemokine regulated on activation of normal T cell expressed and secreted (RANTES), have macrophage chemotactant properties, with MCP-1 being one of the most potent macrophage recruiters. Moreover, studies have suggested that MCP-1 expressed in colonic epithelial cells plays a role in modulating immune responses in inflamed colonic mucosa.

Abbreviations: COX-2, cyclooxygenase 2; MCP-1, macrophage chemotactic protein; PG, prostaglandin; VEGF, vascular endothelial growth factor; RANTES, regulated on activation of normal T cell expressed and secreted; ELISA, enzyme linked immunosorbent assay; MIP, macrophage inflammatory protein; NSAIDs, non-steroidal anti-inflammatory drugs; FAP, familial adenomatous polyposis; H&E, haematoxylin and eosin; PBS, phosphate buffered saline; EDTA, ethylenediaminetetraacetic acid; PNSF, phenylmethylsulfonyl fluoride; FITC, fluorescein isothiocyanate; PBMC, peripheral blood mononuclear cells; FCS, fetal calf serum; UPS, lipopolysaccharide; CHAPS, 3-[3(cholamidopropyl)-dimethylammonio]-1-propane-sulfonate
Thus we hypothesised that –CC chemokines released from epithelial cells in colonic adenoma might be involved in macrophage migration, COX-2 expression in these migrant macrophages and, thereby, in the evolution of colonic adenoma into tumorigenesis. In this study, we investigated expression of various macrophage chemotactic factors in human colorectal adenomas and examined the effect of MCP-1 on COX-2 expression, prostaglandin (PG) E2 release, and vascular endothelial growth factor (VEGF) production in human macrophages.

MATERIALS AND METHODS

Patients and tissue specimens

Tissue samples were obtained from 156 patients (105 males, 51 females; median age 69.84 years; range 40–88) who had undergone colonoscopy due to altered bowel habits or abdominal pain, at the Department of Internal Medicine, Nippon Medical School, Tokyo, Japan. We collected one adenoma sample from each adenoma polyp and normal mucosa, RANTES, MIP-1α, and MCP-1. We also used 10 additional adenoma samples for short term tissue cultivation. Before analysis, the protocol was fully explained to all subjects and written informed consent was obtained.

Chemokine assays

Adenoma tissue samples were homogenised with phosphate buffered saline (PBS) at pH 7.4 containing 2 mmol/l ethylenediaminetetraacetic acid (EDTA), 1 mmol/l phenylmethylsulfonyl fluoride (PMSF) (Sigma Chemical Co, St. Louis, Missouri, USA), and 1 mmol/l sodium pyruvate, 2 mmol/l L-glutamine, 0.1% NaHCO3, 50 μg/ml streptomycin, 100 U/ml penicillin (Gibco-BRL), and 2% fetal calf serum (FCS; Gibco-BRL, Gaithersburg, Maryland, USA). Bovine serum albumin (Seikagaku Kogyo, Tokyo, Japan) was used as a standard. Chemokine concentrations were expressed as pg per mg protein. For each grade of adenoma dysplasia, we compared adenoma chemokine levels with those of normal mucosa from the same patient.

Adenoma tissue culture

To verify that adenoma tissue synthesises chemokines, 10 adenoma and 10 normal colonic mucosa tissue samples were washed twice with PBS immediately after endoscopic polypectomy and then cultured in RPMI-1640 (Nikken, Kyoto, Japan) for three hours at 37°C. Residual tissue samples were fixed, stained with H&E, and analysed immunohistochemically. After three hours of cultivation, tissue samples were homogenised and supernatants used for chemokine analysis, as described above.

Immunofluorescence analysis of human sporadic colonic adenoma

Double immunofluorescence analysis and confocal laser scanning microscopy were used to evaluate colocalisation of COX-2 (diluted 1:5; IBL, Gunma, Japan) and MCP-1 (diluted 1:10; PePro Tech, Rocky Hill, New Jersey, USA). Sections were incubated overnight at 4°C with a mixture of the two primary antibodies. The antibody against COX-2 was allowed to react with a secondary antibody (goat antirabbit IgG; diluted 1:100; Vector Laboratories, Burlingame, California, USA) labelled with Texas red. The antibody against MCP-1 was allowed to react with a secondary antibody (horse antimouse IgG; diluted 1:100; Vector) labelled with fluorescein isothiocyanate (FITC; Sigma Chemical Co.), followed by nuclear counterstaining with 4′, 6-diamidino-2-phenylindole (Sigma Chemical Co.) for 15 minutes to facilitate identification of morphological features.

Sections were also incubated with anti-human COX-2 and anti-CD68 (Dako, Kyoto, Japan) antibodies (both diluted 1:25 in PBS) and followed by incubation with Texas red conjugated goat antirabbit IgG (IgG; CD68; Vector) and FITC conjugated goat antirabbit IgG (COX-2; Vector) for 60 minutes at room temperature. Immunofluorescence was analysed under a laser scanning confocal fluorescence microscope (Leica TCS-4D DMIRBE, Heidelberg, Germany), equipped with argon and argon krypton laser sources.

Isolation of monocytes from human blood

Peripheral blood mononuclear cells (PBMC) were isolated from human blood samples by Ficoll-Paque (Phamacia Biotech, Uppsala, Sweden) centrifugation. PBMCs (2×10⁶/ml) were seeded onto six well plates, incubated in RPMI-1640 supplemented with non-essential amino acids, 2 mmol/l sodium pyruvate, 2 mmol/l L-glutamine, 0.1% NaHCO3, 50 μg/ml streptomycin, 100 U/ml penicillin (Gibco-BRL), and 2% fetal calf serum (FCS;Trace Laboratories, Pataline, Illinois, USA) overnight, and adherent cells allowed to differentiate into macrophages. Monocytes comprised over 85% of these cells, as shown by CD68 staining, and had a viability >90%, as indicated by Trypan blue dye exclusion tests. These cells were stimulated with 10 ng/ml MCP-1 for 24 hours in the presence of FCS, and then harvested and stored at −70°C for western blot analysis. Supernatants were harvested for PGE2 and VEGF measurements.

PBMC preparation for immunocytochemical analysis

Human macrophages (2×10⁶/ml) were plated onto two well Laboratory-Tek chamber slides (Nalge Nunc Intl, Naperville, Illinois, USA). After 24 hours of incubation, with or without MCP-1, cells were fixed in 4% paraformaldehyde for 10 minutes at room temperature and then permeabilised with methanol for 20 minutes at 4°C. Cells were then incubated with anti-CD68 (Novocrosta Laboratories, Newcastle, UK) and anti-COX-2 antibodies, and double immunofluorescence was analysed as described above.

MCP-1 stimulation of PBMC and measurement of PGE2 and VEGF

PBMC were seeded onto each well of six well plates or onto 10 cm dishes at a density of 2×10⁶ cells/ml in either 1% or
10% FCS culture medium. Cells were incubated for 24 hours with either 20 ng/ml lipopolysaccharide (LPS) or 10 ng/ml MCP-1 (Santa Cruz Biotechnology, Inc, Santa Cruz, California, USA) in the presence of 1% or 10% FCS. Thereafter, culture supernatants were used to measure PGE₂ and VEGF concentrations according to instructions in commercially available kits (PGE₂: Assay Designs Inc., Ann Arbor, Michigan, USA; VEGF: Bioskoi, Camarillo, California, USA), as we have shown recently in human gastric fibroblasts. In experiments with COX inhibitors, either 200 nmol/l SC560 (Pharmacia, Newark, New Jersey, USA) or 10 μmol/l celecoxib (Pharmacia), selective COX-1 and COX-2 inhibitors, respectively, were added one hour before MCP-1 stimulation in the presence or absence of PGE₂ (Sigma-Aldrich, St Louis, Missouri, USA). Previous studies have shown that SC560 at 100–300 nmol/l reduces PGE₂ release according to dose, without affecting COX-2 dependent PGE₂ production. Thus we used SC560 at 200 nmol/l in the present study. Celecoxib 10 μmol/l has been shown to inhibit COX-2 dependent PGE₂ production by >90% without affecting cell viability.

Western blot analysis of COX-1 and COX-2 proteins in human macrophages

COX protein in human macrophages was partially purified, as previously reported by Mizuno and colleagues. Macrophages were homogenised in 50 mmol/l Tris HCl (pH 8.0), 0.5 mol/l sucrose containing 1.0 mmol/l PMSF, 1.0 mmol/l peptatin A, and 2.0 mmol/l EDTA. CHAPS (3-[3-cholamidopropyl]-dimethylammonio]-l-propane-sulfonate) (Sigma Chemicals) was added to 1% (wt/vol), and the mixture stirred for two hours at 4°C. After 10 minutes of centrifugation at 15 000 g, the supernatant was loaded onto an anion exchange column equilibrated with 25 mmol/l Tris HCl (pH 8.0) plus 0.4% CHAPS. The fraction eluted at 500 mmol/l NaCl was concentrated to 40% of the initial volume. Samples were separated by sodium dodecyl sulphate-polyacrylamide gel electrophoresis and transferred onto a Hybond-P nitrocellulose membrane (Amersham Life Science, Buckinghamshire, UK) and probed with anti-COX-1 or anti-COX-2 antibody (diluted 1:50, 1:100). Bound antibodies were detected with horseradish peroxidase conjugated antirabbit IgG (diluted 1:2000) using the enhanced chemiluminescence detection system (Amersham Biosciences). Protein concentration was measured with protein assay reagent.

Statistical analysis

Data are presented as means (SEM). The paired t test was used for comparison of chemokine assays for normal colonic mucosa and adenomas in the same patients. PGE₂ and VEGF levels released from human macrophages were analysed by
the non-parametric Mann-Whitney test. The software program Statview was used for data analysis. A p value \( <0.05 \) was regarded as statistically significant.

RESULTS
Chemokine levels in human sporadic colonic adenoma
We measured levels of MCP-1, RANTES, MIP-1\(\alpha\), and MIP-1\(\beta\), all chemokines potentially involved in the migration of macrophages into the subepithelium of colonic adenoma. After pathological examination, each chemokine level was measured in 20 adenoma samples, 10 each for adenomas with mild-moderate or severe dysplasia. Each adenoma sample was matched with its corresponding normal colonic mucosa sample, taken from the same patient, and chemokine levels compared. MCP-1 levels were significantly higher in adenoma than in normal colonic mucosa \( (55.8 \pm 4.2 \mu g/mg \text{ protein}) \), with higher levels seen in samples of colonic adenoma with severe dysplasia \( (227.9 \pm 35.4 \mu g/mg \text{ protein}) \) than in those with mild-moderate dysplasia \( (129.7 \pm 19.9 \mu g/mg \text{ protein}) \) (fig 1A). However, there were no significant differences in chemokine levels for RANTES, MIP-1\(\alpha\), or MIP-1\(\beta\) for all groups tested (fig 1B–D).

MCP-1 synthesis in adenoma tissue cultured in vitro
To verify that elevated MCP-1 levels are derived from the adenoma itself, and not from the peripheral circulation, we cultured adenoma tissue for a brief period and compared MCP-1 levels before and after cultivation. In this experiment, all but one tissue sample was identified as mild to moderate dysplasia by subsequent H\&E analysis of residual tissue samples. Thus nine mild to moderate dysplasia samples were used for the present analysis. MCP-1 levels in both adenoma and normal colonic mucosa significantly increased during three hours of cultivation. These increases were in proportion to basal levels of each tissues type, suggesting that MCP-1 is not derived from the peripheral circulation, but actually synthesised by colonic adenoma themselves (fig 2).

Immunofluorescence analysis of MCP-1 and COX-2 in human sporadic colonic adenoma
Next we examined the immunohistological localisation of MCP-1 and COX-2 in colonic adenoma and normal mucosa. Neither COX-2 nor MCP-1 immunoreactivities were seen in normal colonic mucosa (fig 3D). In contrast, MCP-1 reactivity was detected in the cytoplasm of epithelial cells in both mild to moderate and severe dysplasia adenomas, whereas COX-2 reactivity was detected in stromal cells at the upper border of the lamina propria, just beneath the epithelium of colonic adenomas (fig 3A–C). Figure 3 shows a representative immunofluorescence analysis of adenomas with mild to moderate dysplasia. Although localisation of MCP-1 and COX-2 expression did not vary significantly between mild-moderate and severe dysplasia adenomas, only weak COX-2 expression was seen in epithelial cells of the latter (data not shown).
Immunohistological colocalisation of CD68 and COX-2 in human sporadic colonic adenoma

To examine the possibility that, in colonic adenoma, macrophages express COX-2 in the subepithelium, we performed dual immunohistochemical analysis of COX-2 and CD68 expression in macrophages. Single immunofluorescence in adenomas with mild to moderate dysplasia showed numerous interstitial CD68 positive cells (fig 4A) and a smaller number of interstitial COX-2 positive cells (fig 4B). Dual fluorescence analysis showed COX-2 protein expression largely limited to a subgroup of CD68 positive macrophages (fig 4C–D).

COX-1 and COX-2 expression in MCP-1 stimulated human macrophages

We then examined the effect of MCP-1 on COX-1 and COX-2 expression in human macrophages prepared from PBMC, as described in materials and methods. MCP-1 at 1 and 10 ng/ml stimulated macrophage COX-2 protein expression according to dose, with no effect on COX-1 expression (fig 5). COX-2 expression levels stimulated by 10 ng/ml MCP-1 for 24 hours paralleled those of COX-2 expression stimulated by 20 ng/ml LPS. Neither COX-2 nor COX-1 inhibitors had any effect on COX-2 expression levels stimulated by 10 ng/ml MCP-1.

Immunofluorescence analysis of anti-CD68 and COX-2 antibodies in human macrophages

Although our preparations of human peripheral macrophages were highly purified, contamination by other mononuclear cells present in PBMC could not be avoided. We thus examined whether COX-2 protein induced by MCP-1 stimulation was limited to macrophages, using immunofluorescence staining with anti-COX-2 and anti-CD68 antibodies. When the macrophage preparation was stimulated with 10 ng/ml MCP-1 for 24 hours, no variation was seen in

Figure 4 Colocalisation of cyclooxygenase 2 (COX-2) and CD68 in human sporadic colorectal adenoma by dual labelling immunofluorescence. Five adenoma tissue samples each with mild to moderate dysplasia or with severe dysplasia were used for immunofluorescence analysis. Each panel shows a representative adenoma tissue with mild to moderate dysplasia. (A) Numerous COX-2-positive interstitial cells. (B) CD68 positive macrophages. (C) Colocalisation of COX-2 and CD68 using a dual wavelength filter. (D) 4' , 6-diamidino-2-phenylindole staining emphasises localisation of COX-2 and CD68 dual stained cells.

Figure 5 Western blot analysis showing expression of cyclooxygenase 2 (COX-2) in human macrophages stimulated by macrophage chemoattractant protein 1 (MCP-1). Lower and upper panels indicate COX-1 and COX-2 expression, respectively. Macrophages were incubated for 24 hours: (A) without stimulation; (B) with 1 ng/ml MCP-1; (C) with 10 ng/ml MCP-1; (D) with 10 ng/ml MCP-1, one hour after 10 μmol/l celecoxib pretreatment; (E) with 10 ng/ml MCP-1, one hour after 200 nmol/l SC560 pretreatment; and (F) with 20 ng/ml lipopolysaccharide as a positive control. Thereafter, macrophages were homogenised and western blot analysis was performed as described in materials and methods.
the number or shape of CD68 positive cells, although COX-2 positive staining increased to include ~90% of cultured cells. Double immunostaining clearly showed that all CD68 positive cells expressed COX-2 protein (fig 6), suggesting that cultured macrophages expressed COX-2 protein on MCP-1 stimulation.

Next we measured PGE2 release from macrophages isolated from PMBC in response to MCP-1 by enzyme immunoassay. Macrophages were stimulated with 10 ng/ml MCP-1 in the presence of either 1% or 10% FCS, where PGE2 release increased with FCS concentration even in the absence of MCP-1 (48.3 (10.4) v 150.0 (10.0) pg/ml; p<0.05). However, MCP-1 at 10 ng/ml further stimulated PGE2 release even in the presence of 10% FCS (150.0 (10.0) v 193.3 (11.5) pg/ml; p<0.05). Celecoxib at 10 μmol/l significantly inhibited PGE2 release down to levels below those induced by 1% FCS alone (fig 7). These results suggest that MCP-1 or FCS stimulated PGE2 release was dependent on COX-2.

Next we measured PGE2 release from macrophages isolated from PMBC in response to MCP-1 by enzyme immunoassay. Macrophages were stimulated with 10 ng/ml MCP-1 in the presence of either 1% or 10% FCS, where PGE2 release increased with FCS concentration even in the absence of MCP-1 (48.3 (10.4) v 150.0 (10.0) pg/ml; p<0.05). However, MCP-1 at 10 ng/ml further stimulated PGE2 release even in the presence of 10% FCS (150.0 (10.0) v 193.3 (11.5) pg/ml; p<0.05). Celecoxib at 10 μmol/l significantly inhibited PGE2 release down to levels below those induced by 1% FCS alone (fig 7). These results suggest that MCP-1 or FCS stimulated PGE2 release was dependent on COX-2.

**Figure 6** Immunofluorescence staining of peripheral blood mononuclear cells (PBMCs) cultured in the presence of macrophage chemoattractant protein 1 (MCP-1). CD68 staining of PBMCs after 24 hours of culture without (A) or with (D) 10 ng/ml MCP-1 stimulation, as well as cyclooxygenase 2 (COX-2) staining without (B) or with (E) MCP-1 stimulation. Merged image of (A) and (B) is shown in (C). Merged image of (D) and (E) is shown in (F). 4', 6-diamidino-2-phenylindole staining is seen in (C) and (F).

**Figure 7** Prostaglandin (PG) E2 concentration in supernatant of macrophages isolated from peripheral blood mononuclear cells (PBMCs). PBMCs were cultured in 1% fetal calf serum (FCS) or 10% FCS for 24 hours. PGE2 levels in: (A) culture supernatant of PBMCs without stimulation; (B) with 10 ng/ml macrophage chemoattractant protein 1 (MCP-1) stimulation; (C) with 10 ng/ml MCP-1 stimulation after one hour of 10 μmol/l celecoxib pretreatment. Results are shown as mean (SEM) in a representative of three separate experiments. The error bar indicates the standard error calculated from triplicate samples in a representative experiment. *p<0.05.

**VEGF release in human MCP-1-stimulated macrophages**

We then measured VEGF levels in these cultured media by ELISA. MCP-1 10 ng/ml significantly stimulated VEGF release from human cultured macrophages (1119.3 (38.4) v 1301.0 (22.7) pg/ml; p<0.05). Celecoxib significantly suppressed MCP-1-stimulated VEGF release (1017.6 (76.7) pg/ml; p<0.05), and PGE2 reversed this inhibitory effect according to dose (1559.3 (56.1) pg/ml, with PGE2 at a concentration of 100 μmol/l; p<0.05) (fig 8). Celecoxib did not affect MCP-1-stimulated COX-2 expression (fig 5) and PGE2 reversed the inhibitory effect of celecoxib on VEGF release, suggesting that the inhibitory effect of celecoxib seen in the present study is not due to its toxic effect on macrophages. Therefore, our results suggest a domino effect initiated by MCP-1 stimulation of COX-2 expression in...

to dose. VEGF level stimulated with 20 ng/ml lipopolysaccharide (LPS)
quent PGE2 and VEGF release in macrophages infiltrating
possibility that endogenous MCP-1 release from adenoma
findings in macrophages infiltrating the lamina propria of colonic adenomas, and there induced to express
whether epithelial cells of adenomas do in fact secrete such mucins. Thus the study did not
explain why macrophages migrate into the lamina propria of colonic adenoma and there express COX-2.
However, in the present study, we found that, among chemokines known to have monocyte chemotactant
activity, including MCP-1, MIP-1α, MIP-1β, and RANTES, MCP-1 alone showed higher expression levels in adenoma
epithelial cells than in normal epithelial cells, in the same patient. Furthermore, when we cultured these tissue samples,
found that, here too, MCP-1 was synthesised at higher concentrations in adenomas than in normal colonic mucosa.
MCP-1 is known as the most potent chemotactant involved in macrophage migration. From these data we
can speculate that MCP-1 is involved, not only in macrophage migration into the lamina propria bordering epithelial
cells in adenomas, but also in induction of COX-2.

Although the exact mechanism through which COX-2 promotes tumorigenesis remains unknown, increasing
evidence shows that COX-2 is involved in the promotion of angiogenesis in a variety of tumours: a number of growth
factors, including angiogenic growth factors such as basic fibroblast growth factor and VEGF,25–31 have been shown to
be released from colon cancer cells via a COX-2 dependent pathway. In addition, a close association between macrophage
infiltration and microvessel density has been shown in a number of tumours, such as in melanomas,32 gliomas,33
cervical cancer,34 gastric cancer,35 oesophageal cancer,36 and breast cancer,37 suggesting that both COX-2 and macrophages
may be important in promoting angiogenesis and tumour growth. Furthermore, PGE has been shown to induce VEGF
production in U937 cells, a human macrophage model.38

In the present study, we found that MCP-1 stimulated both
COX-2 expression and VEGF release in human macrophages.
MCP-1 stimulated VEGF release from macrophages was
inhibited in the presence of a selective COX-2 inhibitor.
Reversal of this inhibition on addition of exogenous PGE2
suggests that, in macrophages, PGE2 is a proximate signal for
MCP-1 stimulated VEGF release. It is well known that VEGF
is a key factor in angiogenesis, contributing to colorectal
tumour growth.39 40 Therefore, our data imply that MCP-1 expressed in these adenoma epithelial cells might be, at least
in part, involved in the production of VEGF by macrophages
attracted into the subepithelial lamina propria, thereby
contributing to tumour growth in the colon. However, we
should note that neither MCP-1 stimulation nor celecoxib
inhibition of VEGF release differed much from that seen at
levels induced by FCS stimulation. Thus VEGF release from
adenoma macrophages in vivo may also be regulated by other
yet to be identified factors, in addition to the MCP-1/COX-2
pathway.

We found in the present study that adenoma tissue
samples, when cultured for three hours, synthesised more
MCP-1 protein than normal colonic mucosa samples,
suggesting that MCP-1 mRNA expression and its translation
into MCP-1 protein might also be higher in adenoma than in

**DISCUSSION**

In the present study, we demonstrated for the first time that
MCP-1 stimulates COX-2 expression in human macrophages
isolated from peripheral blood and cultured in vitro. In addition,
MCP-1 stimulated VEGF release via a COX-2/PGE2
autocrine/paracrine pathway in these isolated macrophages.
Furthermore, we found that MCP-1 expression levels were
higher in adenomas than in normal colonic mucosa and
limited exclusively to adenoma epithelial cells. MCP-1
expression levels increased with degree of dysplasia in adenomas; even epithelial cells exhibiting mild dysplasia
expressed higher MCP-1 levels than normal colonic epithelium
in the same patient. In contrast, COX-2 expression was
found only in macrophages immediately beneath epithelial
cells of adenomas expressing MCP-1, in accord with previous
studies.12 13 24 Therefore, these results raise the interesting
possibility that endogenous MCP-1 release from adenoma
epithelial cells is involved in COX-2 induction and subse-
quent PGE2 and VEGF release in macrophages infiltrating
adenoma. Several lines of evidence suggest that COX-2
expressed in macrophages infiltrating the lamina propria
might play a crucial role in the growth and progression
of colorectal adenoma. Firstly, macrophages migrating into the
lamina propria beneath intestinal polyps of mice bearing APC
gene mutations show COX-2 expression, and COX-2 gene
expression in these mice dramatically decreases both polyp
number and size.14 Secondly, cancer cells transplanted into
wild-type mice grow more rapidly than those transplanted
into COX-2 gene knockout mice, suggesting that interstitial
cells expressing COX-2 in the periphery of cancer cells are
crucial for cancer cell growth.25 Thirdly, COX-2 expression
was found in macrophages following their migration into the
lamina propria of colonic adenomas in humans, and in
human FAP, celecoxib, a selective COX-2 inhibitor, has been
shown to prevent colorectal adenoma from progressing into
adenocarcinoma.26 Therefore, to understand each step in
the evolution of adenoma into carcinoma of the colon, it is
essential to first clearly understand the adenoma epithelial
and interstitial cell to cell interactions.

However, to date, the exact mechanism through which macrophages are first stimulated into migrating into the
lamina propria of adenomas, and there induced to express
COX-2, remains unknown. Recently, one possible candidate
as a macrophage COX-2 inducer was isolated from conditioned
media in a colon cancer cell line. The study suggested
that, in the tumour microenvironment, mucus produced by
colon cancer cells are involved in the initial induction of
COX-2.27 However, it is not clear whether epithelial cells of
adenomas do in fact secrete such mucins. Thus the study did not
necessarily explain why macrophages migrate into the
lamina propria of colonic adenoma and there express COX-2.

Cultured macrophages, which in turn stimulates PGE2,
and culminates in VEGF release.
normal colonic mucosa. Nevertheless, it has yet to be determined what regulates MCP-1 expression in adenoma epithelial cells. In mice, APC gene mutations alone induce intestinal polyposis where COX-2 expressing macrophages can be seen in the polyp subepithelium. Similarly, even mild dysplasia adenoma showed higher levels of MCP-1 expression than normal colonic mucosa in the same patient, suggesting that any gene mutation involved in induction of adenomas might also be linked to MCP-1 expression in humans. However, more work is clearly required to identify the exact mechanisms through which MCP-1 expression is induced in epithelial cells, and to elucidate the actual interaction between adenoma epithelial MCP-1, macrophage migration, and COX-2 expression in human colorectal adenoma.
