ABSTRACT

Objective Gastric adenocarcinoma (gastric cancer, GC) is a major cause of global cancer mortality. Identifying molecular programmes contributing to GC patient survival may improve our understanding of GC pathogenesis, highlight new prognostic factors and reveal novel therapeutic targets. The authors aimed to produce a comprehensive inventory of gene expression programmes expressed in primary GCs, and to identify those expression programmes significantly associated with patient survival.

Design Using a network-modelling approach, the authors performed a large-scale meta-analysis of GC transcriptome data integrating 940 gastric transcriptomes from multiple independent patient cohorts. The authors analysed a training set of 428 GCs and 163 non-malignant gastric samples, and a validation set of 288 GCs and 61 non-malignant gastric samples.

Results The authors identified 178 gene expression programmes ('modules') expressed in primary GCs, which were associated with distinct biological processes, chromosomal location patterns, *cis*-regulatory motifs and clinicopathological parameters. Expression of a transforming growth factor β (TGF- β) signalling associated 'super-module' of stroma-related genes consistently predicted patient survival in multiple GC validation cohorts. The proportion of intra-tumoural stroma, quantified by morphometry in tissue sections from gastrectomy specimens, was also significantly associated with stromal super-module expression and GC patient survival.

Conclusion Stromal gene expression predicts GC patient survival in multiple independent cohorts, and may be closely related to the intra-tumoural stroma proportion, a specific morphological GC phenotype. These findings suggest that therapeutic approaches targeting the GC stroma may merit evaluation.

INTRODUCTION

Gastric adenocarcinoma (gastric cancer, GC) is a major cause of global cancer mortality.^{1,2} Treatment of GC patients is currently based on clinical parameters such as age, performance status and

Significance of this study
What is already known on this subject?

- Gene expression profiles of primary cancers can provide 'snapshots' of biological pathways expressed by cancer cells and other cell populations in solid tumours.
- Identifying gene expression programmes associated with patient survival may refine our ability to predict clinical prognosis, discover specific molecular processes regulating disease progression and highlight novel avenues for therapeutic intervention.

What are the new findings?

- This study reports the largest analysis of gastric cancer transcriptomes to date, providing a comprehensive inventory of expression programmes ('modules') present in gastric cancer.
- Of the 178 modules expressed in primary gastric cancers, expression of a transforming growth factor β (TGF- β) associated module of stroma-related genes consistently predicted patient survival in multiple datasets.
- Histopathological analysis of primary gastric cancers revealed that stromal module expression was associated with the proportion of intra-tumoural stroma (ITS).
- Direct histopathological measurement of the ITS proportion was predictive of gastric cancer patient survival.

How might it impact on clinical practice in the foreseeable future?

- Quantifying the proportion of ITS in gastric cancers during routine histopathological assessment may serve as a surrogate marker for stromal gene expression levels in individual tumours.
- Therapies targeting pathways associated with the tumour stroma, such as TGF- β signalling, merit consideration in gastric cancer.

tumour, node, metastasis (TNM) staging,³ which are collectively used to decide whether a patient should be treated by surgery alone, surgery plus chemotherapy/chemoradiation or chemotherapy alone. Of these, TNM staging is the major tool used by clinicians to predict GC patient prognosis. However, GC patients with the same TNM stage often exhibit distinct clinical outcomes⁴ suggesting the existence of additional factors influencing GC disease aggressiveness. Previous studies attempting to identify additional GC prognostic factors have investigated a variety of clinical, histological (morphological subtypes, grade of differentiation) and molecular factors, including Ki67 expression (a marker of cell proliferation), p53 mutation status, DNA ploidy and human epidermal growth factor receptor 2 (HER2) expression.^{5–9} However, clear prognostic roles have not been consistently observed for most of these factors, particularly when tested in multiple independent patient cohorts. So far, prognostic studies in GC have focused primarily on aberrations occurring in the GC cell. However, like all solid tumours, GCs are highly complex entities composed of neoplastic epithelial cells, as well as of vessels, fibroblasts, immune cells and extracellular matrix. Compared with cancer cells, relatively little is known regarding the potential contribution of these other components to GC patient prognosis.^{10–13}

Gene expression profiling represents a powerful technology that can provide an unbiased and holistic ‘molecular snapshot’ of distinct gene expression programmes present within a tumour.¹⁴ While some of the genes comprising these expression programmes are expressed exclusively by cancer cells, other cell types within a tumour may also contribute to the gene expression profile. Here, we hypothesised that a detailed analysis of a large number of GC transcriptomes would provide a comprehensive inventory of distinct expression programmes associated with GC, which can then be tested for associations with patient prognosis. Analysing gene expression data from 940 GCs and non-malignant gastric tissues from different patient populations, we found that the expression of a ‘stromal module’ comprising stroma-related genes was associated with both, transforming growth factor β (TGF-β) signalling and patient survival in multiple GC cohorts. In GC tissue sections, we further found that the proportion of the stroma within GCs (intra-tumoural stroma, ITS) also predicted patient survival. To our knowledge, this is the first study demonstrating a prognostic role for both, stromal gene expression and the ITS proportion in GC patients. Our results highlight the potential role of the ITS proportion as a predictive biomarker to identify subgroups of patients with GCs that might respond to tumour stroma-directed therapies. Moreover, because our molecular analysis indicates that the GC stromal module is associated with TGF-β signalling, molecular therapies targeting the TGF-β pathway may merit evaluation in GC patients.

METHODS

Gastric cancer datasets

Discovery datasets

The GC coexpression network was generated using nine independent GC expression microarray datasets (supplemental table 1), comprising 591 gastric samples (428 GCs and 163 non-malignant samples (normal gastric mucosa, chronic gastritis, atrophic gastritis with intestinal metaplasia)). One hundred and nine of the 163 non-malignant gastric samples were matched to GC samples, while the remaining 54 non-malignant samples were gastric biopsies from individuals with *Helicobacter pylori* gastritis without cancer, recruited into a randomised, placebo-controlled trial of *H. pylori* therapy.¹⁵ The datasets were

obtained from the National Center for Biotechnology Information (NCBI) Gene Expression Omnibus (<http://www.ncbi.nlm.nih.gov/geo/>), or from collaborators (SG-2, LS-1 and AMS). Several of these datasets have been previously published.^{15–20} Detailed clinical information from the discovery datasets was not used in this study, with the exception of the AMS cohort (34 GCs) which was analysed to provide additional power for the survival analysis.

Validation datasets (transcriptome)

Three GC datasets (SG-3, AU-2 and YGC) were used for validation analyses comprising 288 GC and 61 non-malignant gastric samples. These samples were not used in the discovery phase. All 61 non-malignant validation samples were matched with a GC. Seven patients received neo-adjuvant therapy (one patient, SG-3 cohort; six patients, AU-2 cohort). Clinical characteristics are presented in table 1. Primary GCs were collected with patient consent from the participating centre’s tissue repositories or pathology archives and approval from the respective institutional research ethics review committees in accordance with local regulations and legislations. Clinical information was collected with the approval of the Institutional Review Board. Gene expression data of these validation datasets have been deposited under Gene Expression Omnibus accession numbers GSE15459 (SG-3), GSE35809 (AU-2) and GSE13861 (YGC).²¹

Validation dataset (tissue microarray (TMA))

An additional GC TMA dataset (LS-2) was also analysed. TMAs were constructed from an independent set of 163 GC patients who underwent curative D2 resection at the Academic Department of Surgery, Leeds General Infirmary, Leeds, UK, between 1970 and 1991. After excluding technical failures and data from patients who died within 30 days after surgery (post-operative mortality), results from 131 patients were available for analyses. Median follow-up time after surgery was 5.5 years ranging from 0.11 years to 20.6 years. Forty-nine (37.4%) patients had died due to cancer at the end of the study period. Clinical characteristics of the LS-2 TMA dataset are presented in the online supplemental table 2.

The supplemental methods provide details of GC network construction, functional annotation of network modules, mapping of modules and oncogenic pathways to individual samples, clinicopathological and survival analyses, and quantitation of ITS by computerised point counting.

RESULTS

Network analysis identifies multiple conserved gene expression modules in GC

We established a discovery series of 591 gastric tissue samples (428 cancers and 163 matched non-neoplastic samples), drawn from nine independent GC transcriptome datasets representing a wide variety of GC patient populations from different countries, including countries with low and high GC incidence (online supplemental table 1). We used these discovery datasets to construct a GC gene coexpression network. First, we established a core network of genes commonly present in all nine datasets comprising genes exhibiting consistent and robust expression correlations in both, GCs and non-malignant gastric samples (see Methods, figure 1A). Second, to increase the number of genes in the network, we expanded the network construction to all possible combinations of eight, seven and six datasets. This network construction method yielded a final GC coexpression network comprising 3177 genes linked by 14 965

'ND' data is not available.

Three independent datasets (Singapore (SG-3), Australia (AU-2) and South Korea (YGC)), comprising 349 samples (288 tumours and 61 non-malignant gastric samples) not included in the initial network construction, were used to validate the coexpression network.

interactions (false discovery rate (FDR) <0.001, supplemental table 3, figure 1A).

To partition the network into meaningful and biologically relevant subunits, we then defined 'modules' within the coexpression network, defined as groups of genes showing a high degree of internal coexpression relative to genes external to the group. Using a previously described module construction algorithm,²² we identified 178 coexpression modules in the network comprising 10–200 genes each (supplemental figure 1, supplemental document 1; supplemental table 4 presents a representative module). Supporting the biological relevance of the GC network, network topology analyses at multiple levels, for example, between (1) all individual genes in the entire coexpression network, (2) all modules and (3) genes within a particular module revealed that the identified networks all exhibited a 'scale-free' structure with most genes acting as 'edges', and certain genes acting as 'hubs' (supplemental figure 2 and supplemental table 5; also see Discussion). These findings are consistent with previous studies establishing that biological networks are often scale-free.²³

Since coexpressed genes typically act within the same pathway or share related biological functions,²⁴ we proceeded to systematically annotate the 178 modules in the coexpression network by comparing their gene content against the Molecular Signatures Database (MSigDB), a publicly accessible database of gene sets annotated by chromosomal position, pathway components, gene ontologies and *cis*-regulatory binding sites (figure 1B). A total of 148 (83%) of 178 modules were successfully mapped to at least one MSigDB dataset at the threshold level of significance ($p<0.001$, minimum overlap >5 genes), while 30 modules lacked MSigDB assignments and may be novel. Several modules shared similar MSigDB annotations raising the possibility that these modules might participate in common biological programmes. We called these higher order associations 'super-modules', and identified seven distinct super-modules in the coexpression network. One super-module comprised 32 modules related to various aspects of cell cycle and

proliferation.²⁵ A second super-module, designated the 'stromal super-module', contained 23 modules associated with extracellular matrix biology and stromal cells. The remaining super-modules in the coexpression network were associated with immune response, digestive function, mitochondrial, ribosomal and proteasomal function (see colour legend in figure 1B). Supplemental document 1 provides all the member genes of the 178 modules, and supplemental document 2 provides a comprehensive table of the 178 modules and their MSigDB assignments.

Determining levels of module expression in individual validation samples

To compare the expression levels of different modules between individual GCs, we used a previously published algorithm (GENOMICA, see Methods and Segal *et al*, 2004²⁶) to map the 178 expression modules onto three independent GC datasets not used in the network construction described above (Singapore dataset: SG-3, 153 GCs and 38 matched non-malignant gastric samples; Australia dataset: AU-2, 70 GCs and 9 non-malignant samples; South Korea dataset: YGC, 65 GCs and 14 matched non-malignant samples). Table 1 provides the clinicopathological characteristics of these datasets. To maximise statistical power, we combined all samples from these datasets (SG-3, AU-2 and YGC) resulting in a combined validation series of 349 samples (288 GCs and 61 non-malignant gastric samples).

Mapping of the expression modules to this combined validation series confirmed that the modules were differentially expressed across individual GCs (figure 2A). We noted interesting relationships between modules. For example, GCs with high expression of cell proliferation modules tended to coexpress modules related to digestive function, while GCs with high expression of the stromal module exhibited low expression of cell proliferation modules and low expression of modules related to digestive function. A subset of GCs showed high expression of modules related to proteasomal function (see Discussion).

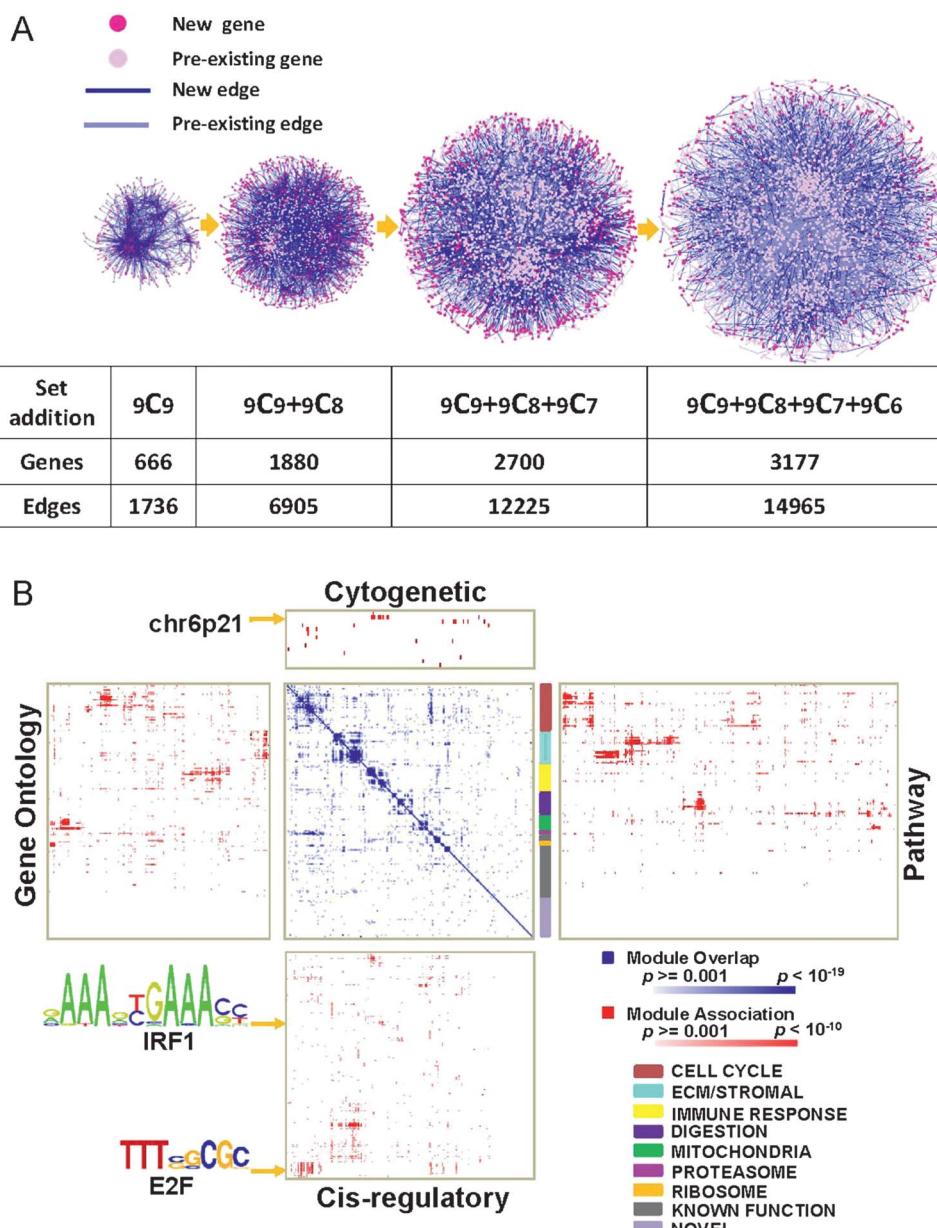

Figure 1 Gastric cancer (GC) coexpression network construction and annotation. (A) Network construction. (left to right) Core network exhibiting conserved coexpression correlations across 9 GC datasets (${}^9\text{C}_9$). Genes are nodes (pink) and edges are coexpression correlations (blue). The core network was expanded by adding nodes and edges across all possible combinations of 8, 7 and 6 GC datasets (${}^9\text{C}_8$, ${}^9\text{C}_7$, ${}^9\text{C}_6$). Light pink nodes represent pre-existing nodes already present in the prior network, while dark pink nodes represent new genes. Light blue lines represent pre-existing edges from the prior network, while dark blue lines represent new edges. All genes and edges are associated with a false discovery rate <0.001 . (B) Functional annotations of modules. (blue-white heat map) Gene composition overlap between the 178 modules. Darker blue regions represent modules with significant gene overlap. The white-blue scale bar indicates p values for the module overlap (hypergeometric test). (Surrounding four red matrices) Module mapping against the Molecular Signatures Database (MSigDB); cytogenetic location (top), pathway signatures (right), *cis*-regulatory binding sites (bottom) and gene ontologies (left). Darker red areas represent significant module associations (minimum overlap number of genes = 5). The white-red scale bar indicates the p values for the module association. The multicoloured vertical colour bar to the right of the white-blue heat map represents groups of modules exhibiting significant overlap in gene content (super-modules, see colour code at bottom right). Arrows indicate representative *cis*-regulatory motifs (E2F, IRF1) and chromosomal bands (6p21). E2F- and IRF1-binding motifs are shown using standard position-weight matrix terminology.

GC expression modules are associated with distinct clinicopathological characteristics

We used the combined validation series to explore if expression of any of these modules might be related to clinicopathological characteristics including age, gender, disease stage, histopathological subtype and grade of differentiation (figure 2A and supplemental table 6). The results from the

combined validation series are presented in the paragraphs below and in supplemental table 6, while the results from analyses of the individual datasets can be found in supplemental figure 3 and supplemental table 7. For these and all subsequent analyses, p values were corrected for multiple hypotheses testing, and a corrected p value <0.05 was considered significant.

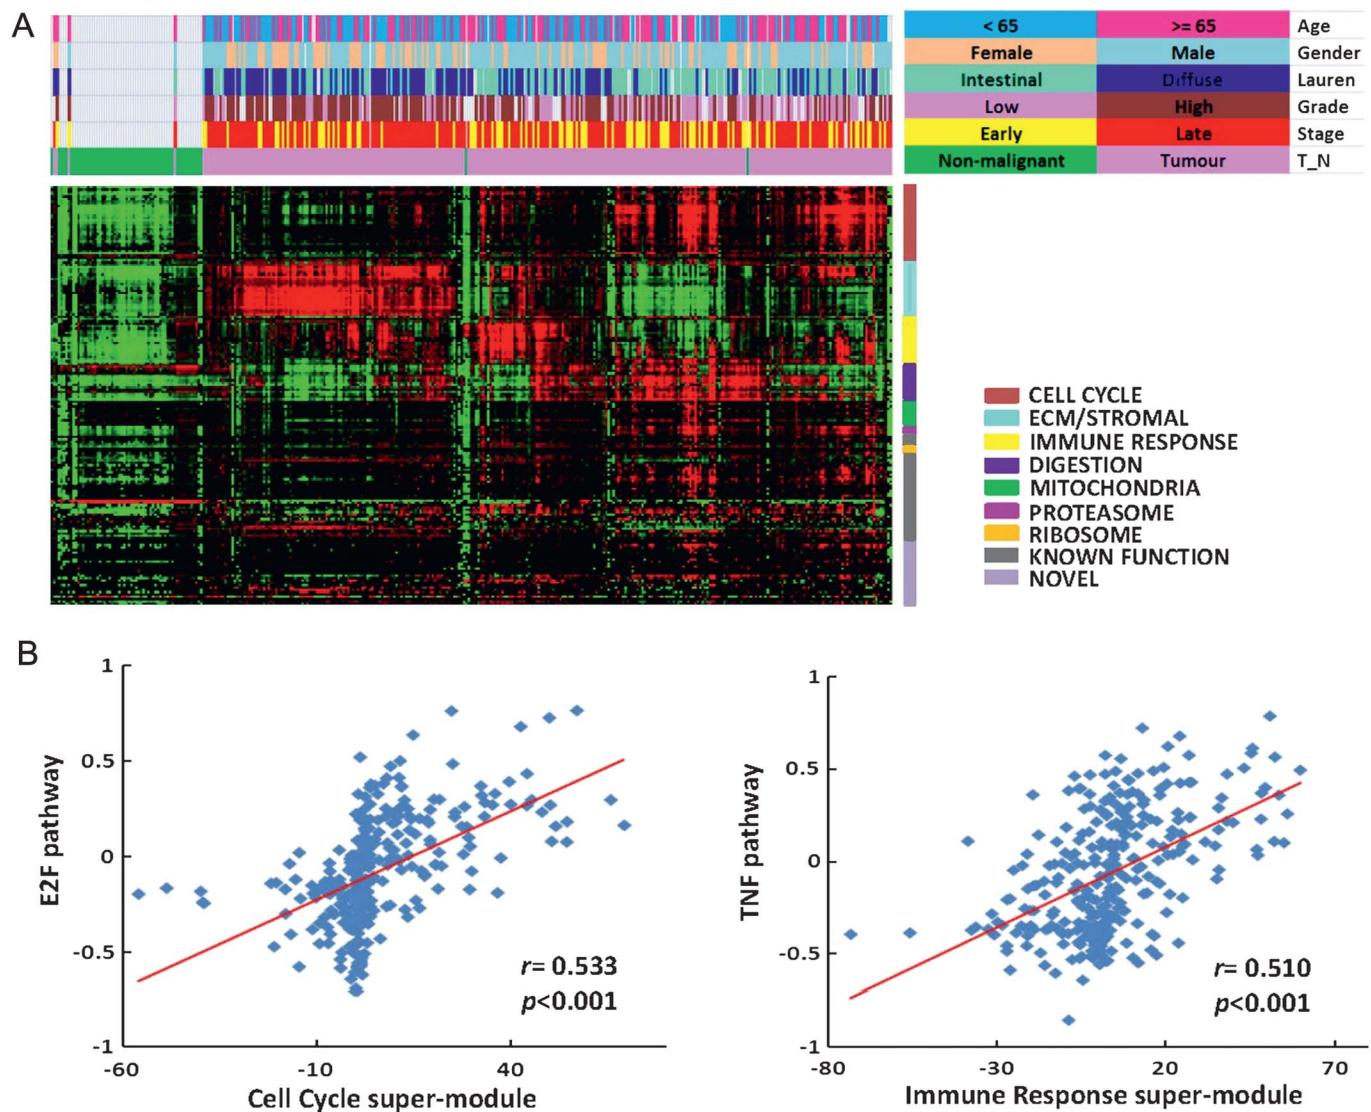

Figure 2 Patterns of module expression are associated with distinct clinicopathological characteristics and oncogenic pathways. (A) The lower red-green heat map represents different patterns of module expression in the combined validation series SG-3/AU-2/YGC dataset (349 samples) ordered by hierarchical clustering. Red represents modules that are highly expressed, while green represents modules expressed at low levels. Coloured bars above the heat map represent clinicopathological characteristics (age, gender, Lauren classification, grade of differentiation, TNM stage, gastric cancer or non-malignant gastric tissue) (colour legend on top right). (B) Oncogenic pathways associated with modules and super-modules. Data originates from the 288 gastric cancers in the 349 combined validation series: SG-3 (n=153), AU-2 (n=70) and YGC (n=65). (Left) E2F pathway activation was significantly correlated with cell-cycle super-module expression (correlation coefficient $r=0.533$, $p<0.001$). The y axis represents levels of E2F pathway activation, while the x axis represents levels of cell-cycle super-module expression. Each data point represents an independent validation sample. (Right) Tumour necrosis factor (TNF) pathway activation correlated with immune response super-module expression (correlation coefficient $r=0.510$, $p<0.001$). The y axis represents levels of TNF pathway activation, while the x axis represents levels of immune response super-module expression.

Age at diagnosis

GCs from patients younger than 65 years of age exhibited higher stromal and immune response super-module expression (stromal: $p<1.00\times 10^{-323}$; immune response: $p=6.69\times 10^{-3}$), while GCs from patients older than 65 years of age exhibited higher cell cycle ($p=1.47\times 10^{-7}$), mitochondrial ($p=4.99\times 10^{-3}$) and ribosomal ($p=0.028$) super-module expression.

Gender

GCs from male patients were associated with higher cell cycle ($p<1.00\times 10^{-323}$) and proteasomal ($p=9.1\times 10^{-4}$) super-module expression, while GCs from female patients were associated with higher stromal super-module expression ($p<1.00\times 10^{-323}$).

Disease stage (UICC (Union for International Cancer Control)/AJCC (American Joint Committee on Cancer) 6th edition)

Early-stage (stages I and II) GCs were associated with higher cell cycle ($p=4.32\times 10^{-9}$), mitochondrial ($p=7.68\times 10^{-9}$), ribosomal ($p=5.87\times 10^{-3}$) and proteasomal ($p=0.035$) super-module expression, while late-stage (stages III and IV) GCs were associated with higher stromal super-module expression ($p<1.00\times 10^{-323}$).

Histopathological subtype

Intestinal-type GCs exhibited higher cell cycle ($p<1.00\times 10^{-323}$), proteasomal ($p=4.95\times 10^{-14}$), digestive function ($p=6.97\times 10^{-13}$), mitochondrial ($p=3.0\times 10^{-3}$) and immune response super-module expression ($p=3.45\times 10^{-3}$), while

diffuse-type GCs were associated with higher stoma super-module expression ($p < 1.00 \times 10^{-323}$).

Grade of differentiation

Well and moderately differentiated, low-grade GCs exhibited higher cell cycle ($p < 1.00 \times 10^{-323}$), digestive function ($p < 1.00 \times 10^{-323}$), mitochondrial ($p = 2.93 \times 10^{-9}$) and proteasomal ($p = 5.49 \times 10^{-7}$) super-module expression, while poorly differentiated and undifferentiated, high-grade GCs were associated with higher stromal ($p < 1.00 \times 10^{-323}$) and immune response ($p = 1.08 \times 10^{-5}$) super-module expression. We also considered the current WHO guideline that differentiation should only be graded in intestinal-type GCs.²⁷ When our analysis was restricted to intestinal-type GCs, low-grade GCs exhibited higher digestive function ($p = 5.10 \times 10^{-7}$) and mitochondrial ($p = 0.002$) super-module expression, while high-grade GCs were associated with higher immune response ($p = 1.20 \times 10^{-15}$) and stromal ($p = 0.027$) super-module expression.

Supporting the robustness of the above associations, similar trends were also observed for the vast majority of these relationships (61 of 69) when the three independent validation datasets (SG-3, AU-2 and YGC) were analysed individually. Only eight relationships showed an opposite trend in the individual sets compared with the combined 349-sample set, and of these eight, only one was significant (Laurén classification and cell-cycle module expression in YGC cohort, p value < 0.05 , supplemental table 7).

GC expression modules are associated with distinct oncogenic pathways

Besides investigating the association with clinicopathological characteristics, we also sought to link the expression of the 178 modules to molecular signalling pathways known to be activated or deregulated in malignant tumours. Using a previously described pathway mapping approach, we mapped specific gene expression signatures ('pathway signatures') representing 21 oncogenic and tumour suppressor pathways previously implicated in gastric carcinogenesis (p53, EGFR, TGF- β , STAT3, VEGF, CEBP, AKT, BRCA1, HER2, SRC, E2F, TNF, MYC, WNT, NF- κ B, PI3K, PPARG, p63, RAS, CD31 and HSP90^{28–30}) onto the combined validation series. We then identified specific GC modules whose expression was significantly correlated to the expression of the pathway signatures (online supplemental tables 8 and 9).

E2F is a transcriptional regulator of cell-cycle genes.³¹ We found that GCs expressing high levels of E2F pathway activation also expressed 32 distinct cell-cycle-related modules ($r = 0.533$, $p < 0.001$; figure 2B, left panel). Supporting E2F as a transcriptional regulator of these modules, a promoter analysis of genes in these cell-cycle-related modules revealed that they were significantly enriched in E2F binding motifs ($p = 2.41 \times 10^{-7}$; figure 3A).

GCs exhibiting high levels of Tumour Necrosis Factor (TNF) and Nuclear Factor Kappa-light-chain-enhancer of activated B cells (NF- κ B) pathway activation also expressed multiple

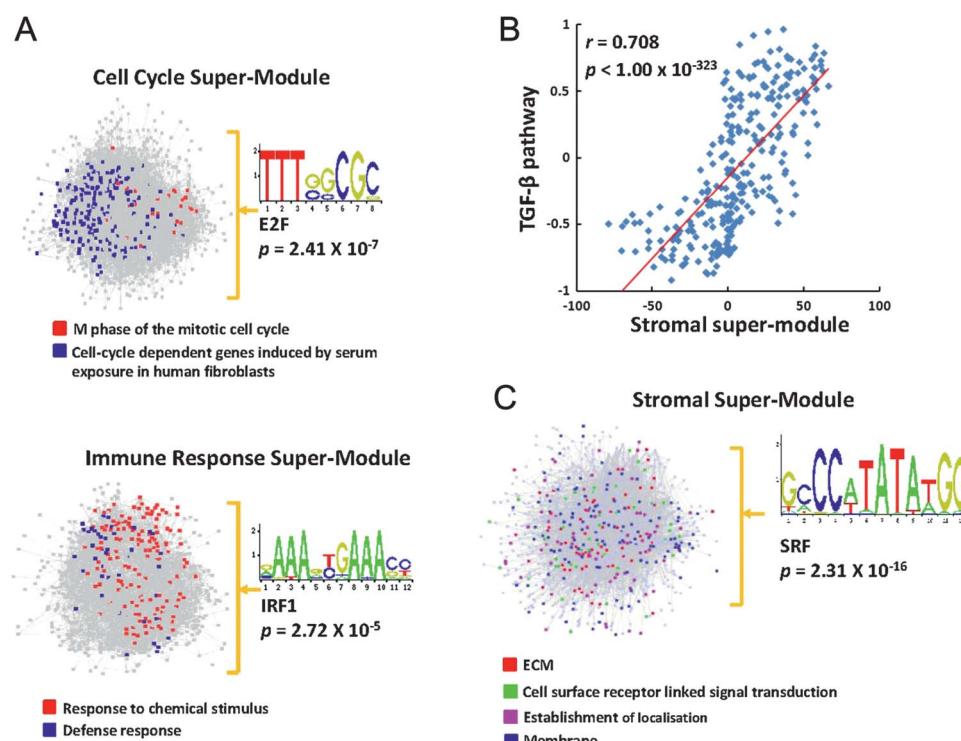

Figure 3 Oncogenic pathways and module expression. (A) Transcription factor-binding motifs in super-modules. Network diagrams depict the cell cycle and immune super-modules. Blue and red points represent distinct modules within the larger super-module. E2F consensus binding sites were significantly enriched in genes of the cell cycle super-module ($p = 2.41 \times 10^{-7}$), while IRF1 consensus binding sites were significantly enriched in genes of the immune super-module ($p = 2.72 \times 10^{-5}$). Position-weight matrix depictions of E2F1- and IRF1-binding motifs are shown. (B) Correlation of TGF- β pathway with stromal super-module expression in the 288 GCs (correlation coefficient $r = 0.708$, $p < 1.00 \times 10^{-323}$). The y axis represents levels of TGF- β pathway activation, while the x axis represents levels of stromal super-module expression. Each point depicts an independent sample. (C) Enrichment of serum response factor transcription factor-binding motifs in the stromal super-module ($p = 2.31 \times 10^{-16}$). Green, pink and red points in the network diagram represent distinct modules within the super-module.

modules related to immune function ($r=0.510$, $p<0.001$; figure 2B, right panel). A promoter analysis of genes from the immune modules revealed that they were characterised by an enrichment of NF- κ B target genes ($p=1.51\times 10^{-6}$, hypergeometric test) and genes with interferon regulatory factor 1 (IRF1)-binding motifs ($p=2.72\times 10^{-5}$; figure 3A). IRF1 has been described as a major downstream target of both TNF and NF- κ B signalling.³²

Expression of the stromal super-module was associated with elevated levels of TGF- β pathway activation in both, the combined validation series and the individual datasets ($r=0.708$, $p<1.0\times 10^{-323}$; figure 3B and online supplemental figure 4). Moreover, expression of the TGF- β ligands TGF- β 3 and TGF- β 1, and also the TGF- β receptors TGF- β R1, TGF- β R2 and TGF- β R3 was consistently higher in GCs with high stromal super-module expression (all p values <0.001 ; online supplemental table 10). A promoter analysis of genes in the stromal super-module revealed that they were significantly enriched in genes with serum response factor-binding motifs ($p=2.31\times 10^{-16}$; figure 3C), a transcription factor known to be activated by TGF- β signalling.^{33–35} These results suggest that TGF- β signalling may regulate the expression of the stromal super-module in GC.

Similar to the clinicopathological characteristics, associations between the expression modules and oncogenic pathways observed in the combined validation series were largely preserved when the three independent validation datasets (SG-3, AU-2 and YGC) were analysed individually (online supplemental table 9).

Expression of the stromal super-module in GCs predicts overall survival

Surveying the different expression modules, we identified a significant relationship between the expression level of the stromal

super-module in GC and patient survival. Specifically, in the combined validation dataset, univariate Cox regression analysis treating stromal super-module expression as a continuous variable in the model revealed that GCs with a high level of stromal super-module expression were associated with significantly poorer overall survival ($p=0.025$; HR 1.007, 95% CI 1.001 to 1.013; table 2). Similar results were observed in a Kaplan-Meier survival analysis, comparing the 1/3 of patients with high stromal super-module expression with the 1/3 of patients with low stromal super-module expression ($p=0.004$, log-rank test; figure 4). Adverse survival trends of patients with GCs exhibiting high stromal super-module expression were also observed when the individual datasets were analysed ($p=0.043$ (SG-3); $p=0.045$ (YGC); $p=0.23$ (AU-2); online supplemental figure 5). Further supporting the association between patient survival and stromal super-module expression, a significant relationship with patient survival was also observed in a fourth dataset (AMS, $n=34$; comparing top vs bottom tertiles), which was used in the initial construction of the coexpression data, and for which clinical outcome data was available ($p=0.018$; online supplemental figure 5).

To compare the prognostic significance of stromal super-module expression with current gold standard clinicopathological criteria of patient prognosis prediction, we performed multivariate Cox regression analysis incorporating stromal super-module expression (continuous variable), age (<65 years vs ≥ 65 years), gender, resection margin status (R0 vs R1), morphology (intestinal-type vs diffuse-type vs mixed type), grade of differentiation (well vs moderate vs poor) and pathological tumour stage according to TNM classification (UICC/AJCC 6th edition). In the combined validation series, the prognostic value

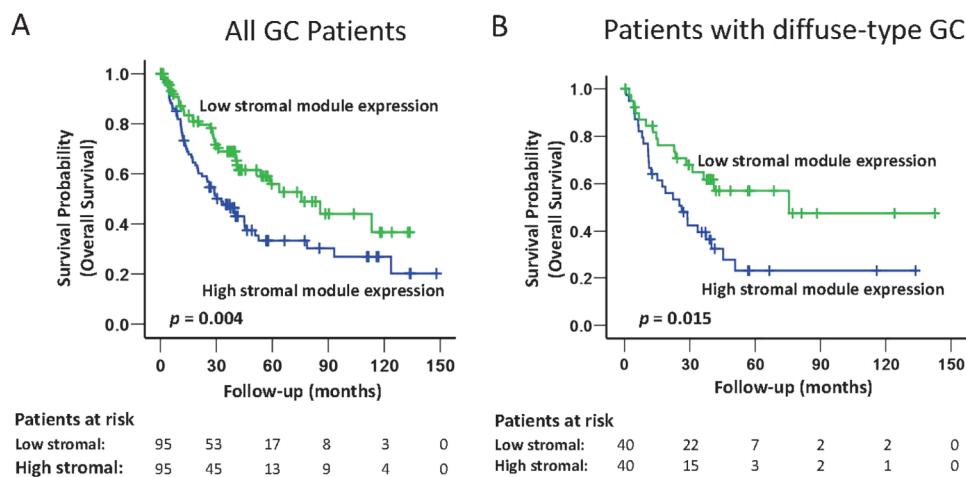

Figure 4 Stromal super-module expression predicts patient survival in the cancers from the combined validation dataset, and in patients with diffuse-type gastric cancer (GC). (A) Expression of the stromal super-module predicts all GC patient survivals in the combined validation dataset. All GC patients were divided into three equally sized groups based on the level of stromal super-module expression: high stroma (top 1/3), moderate stroma (middle 1/3), and low stroma (bottom 1/3). Kaplan–Meier analysis was used to compare overall survival probability from the time of surgery of patients with either high stroma (top 1/3) or low stroma (bottom 1/3) GC. GC patients with high levels of stromal super-module expression had a poorer prognosis ($p=0.004$, log-rank test). (B) Stromal super-module expression levels predict patient survival in patients with diffuse-type GC. One hundred and eighteen patients with diffuse-type GC (combined SG-3/AU-2/YGC data) were divided into three equally sized groups based on levels of stromal super-module expression: high stroma (top 1/3), moderate stroma (middle 1/3), and low stroma (bottom 1/3). Kaplan–Meier survival analysis demonstrates that patients with diffuse-type GC and high levels of stromal super-module expression (top 1/3, $n=40$) had poorer survival than patients with diffuse-type GC and low levels of stromal super-module expression (bottom 1/3, $n=40$) ($p=0.015$, log-rank test).

of stromal super-module expression was related to disease stage ($p=0.12$, HR: 1.005, 95% CI 0.999 to 1.012; table 2). A stage-adjusted analysis revealed that the association between stromal super-module expression and survival was primarily observed in stages III and IV (ie, late stage) disease ($p=0.024$ for stages III and IV compared with $p=0.668$ for stages I and II; online supplemental table 11). Kaplan–Meier survival analysis restricted to stage III GC patients showed that patients with GCs expressing high levels of stromal super-module expression had a poorer prognosis compared with patients with low stromal super-module expression ($p=0.039$; online supplemental figure 6).

Besides survival, high expression of the stromal super-module was significantly associated with diffuse-type morphology ($p<1.00\times 10^{-323}$; online supplemental table 6), a histological subtype traditionally associated with clinically poor prognosis.^{36 37} In a subgroup analysis of diffuse-type GCs in the combined validation set, we found that patients with diffuse-type and high stromal super-module expressing GCs exhibited a significantly poorer survival compared with patients with diffuse-type and low stromal super-module expressing GCs ($p=0.015$; figure 4B). This result suggests that additional information beyond histological classification may be revealed by measuring stromal super-module expression, supporting recent reports describing distinct subtypes of diffuse-type GC.³⁸

To validate our results using a non-array technology, we performed immunohistochemistry on GC full sections for two proteins, vimentin (VIM) and caldesmon (CALDESM), whose mRNA expression was highly correlated with stromal super-module expression (see Methods for selection criteria). In the LS-1 dataset, VIM protein expression exhibited a trend towards association with stromal super-module expression ($r=0.34$, $p=0.08$). Similarly, CALDESM protein expression tended to be positively associated with stromal super-module expression ($r=0.22$, $p=0.26$; online supplemental figure 7). We think it not surprising that there is only a trend and no significant correlation between the IHC results and the stromal super-module expression, as the former is based on measurements of a single

biomarker (eg, VIM or CALDESM protein), while the latter is based upon the coordinated expression levels of 878 genes, which is likely to be more robust.

Stromal super-module expression is related to the intratumoural stroma proportion

We hypothesised that GC stromal super-module expression levels might be correlated with specific histopathological features observable in routine haematoxylin & eosin (H&E)-stained sections of GCs. To explore this possibility, we analysed two GC datasets, representing cases for which we were able to obtain full H&E sections of sufficient quality for histological analysis, and corresponding gene expression data. These included (1) 156 GCs comprising 119 SG-3 GCs, and an additional 37 GCs that were subsequently recruited in the course of this study ('Expanded SG-3') and (2) all 29 GCs in the LS-1 dataset. Genomic and histological analysis confirmed that the GCs exhibited highly variable stromal super-module expression across individual GCs (figure 5A for LS-1). A representative H&E-stained section was selected from each case and scanned using an Aperio scanner. To quantify the proportions of the different components within the cancer (eg, cancer cells, stroma including fibroblasts and extracellular matrix, tumour lumen, necrosis, vessels, inflammatory cells), we used a computerised morphometric method (point counting, see online supplemental methods), previously applied to colon cancer³⁹ and formally described by Weibel.⁴⁰ The set of investigated GCs exhibited diverse histopathological phenotypes with respect to tumour cell density, intra-tumoural stroma, vascularity and immune cell infiltrates (figure 5B and C). We detected a significant positive correlation between the expression of the stromal super-module and the morphometrically quantified proportion of intra-tumoural stroma in both, the expanded SG-3 and LS-1 datasets (SG-3: median ITS: 60%, range: 15–99%, correlation coefficient $r=0.327$, $p=3.14\times 10^{-5}$, figure 5D; LS-1: 29 GCs, median ITS: 47%, range: 3–88%; correlation coefficient $r=0.426$, $p=0.021$; online supplemental figure 8). The

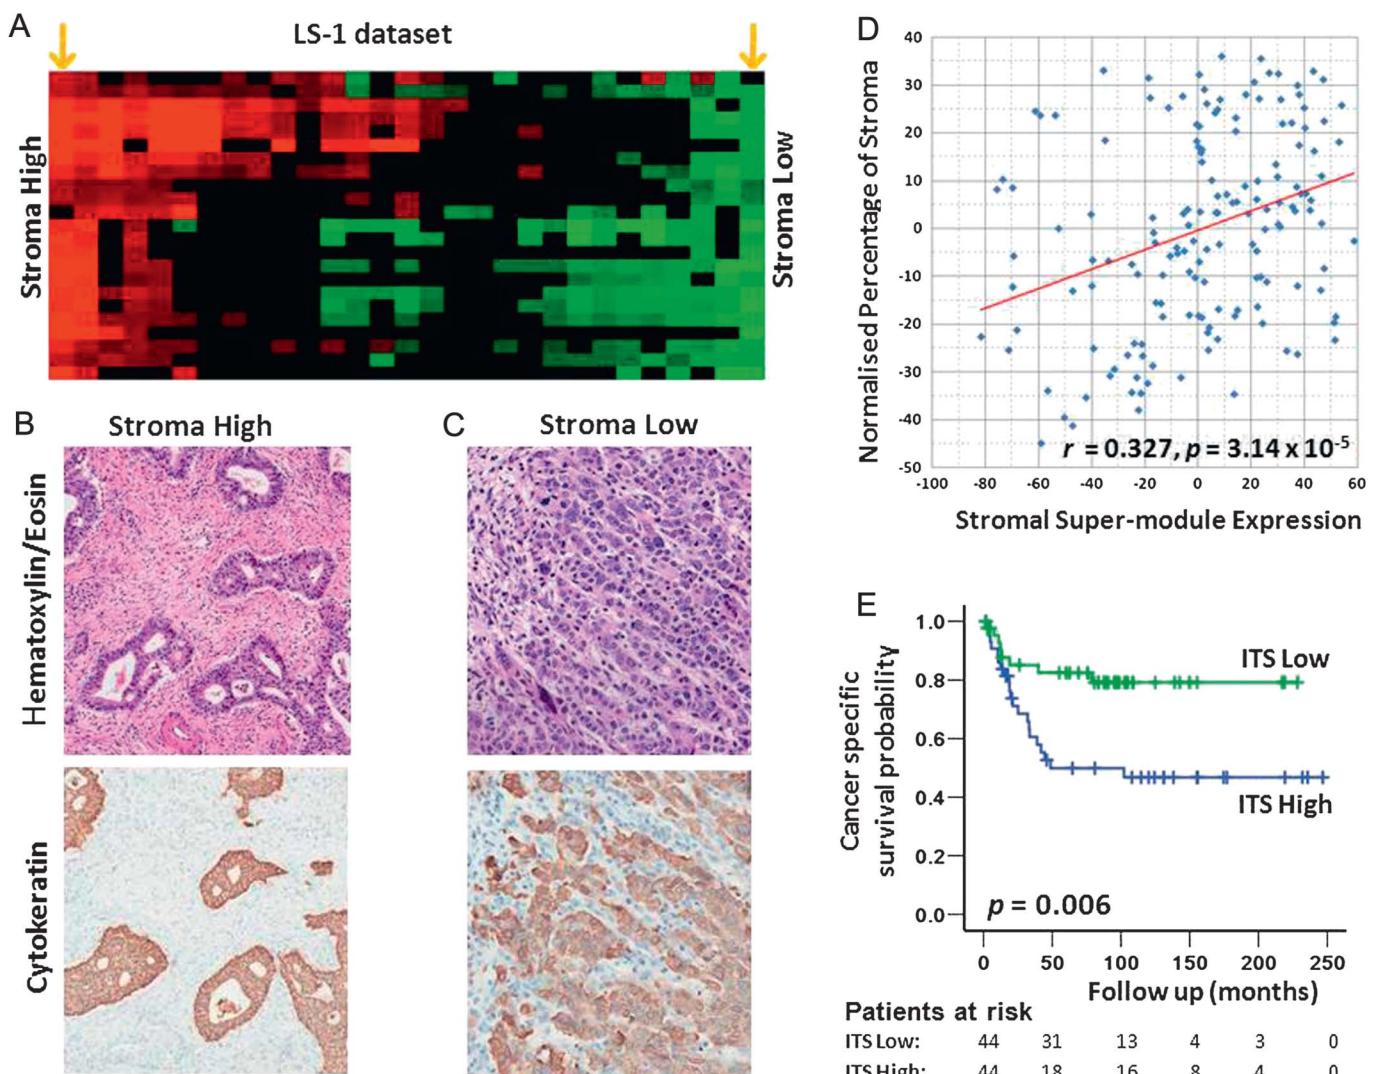

Figure 5 Association of intra-tumoural stroma (ITS) proportion with stromal super-module expression and patient survival. (A) Stromal super-module expression of gastric cancers (GCs) in the LS-1 dataset ($n=29$). Columns represent individual GCs, rows represent individual stromal modules. Red, high stromal super-module expression, green, low stromal super-module expression. The orange arrows at the extreme left and right represent GCs selected for figure 5B and C. (B) and (C) Representative H&E-stained sections of GCs (top panel) illustrating prominent differences in ITS between a GC with high stromal super-module expression (B) and a GC with low stromal super-module expression (C). Consecutive sections from the same blocks subjected to cytokeratin (CK) immunohistochemistry to facilitate visualisation of GC tumour cells (brown). The intra-tumoural stroma was CK negative (blue due to the haematoxylin counterstain). (D) Association of stromal super-module expression with the ITS proportion in the expanded SG-3 dataset. The y axis represents the normalised ITS proportion measured by morphometry (see Methods). The x axis represents the expression level of the stromal super-module. Each point represents an individual GC. A significant positive correlation was observed (correlation coefficient $r=0.327$, $p=3.14 \times 10^{-5}$). (E) 131 GCs from LS-2 were divided into three equal-sized groups based on the levels of ITS, for example GCs with high, moderate or low ITS proportion. Kaplan–Meier analysis demonstrates that patients with GCs exhibiting a high ITS proportion (blue line) have poorer cancer-specific survival compared to patients with low ITS proportion GCs (green line, $p=0.006$, log-rank test).

association between stromal super-module expression and ITS proportion remained significant after correcting for stage, age, gender, Laurén classification and grade (expanded SG-3: $p=0.002$; LS-1: $p=0.024$; partial correlation analysis⁴¹). This result suggests that the expression level of the stromal super-module in GCs may be directly related to the proportion of ITS measured in H&E-stained tissue sections.

To further investigate the stromal super-module expression/ITS proportion association, we tested whether the ITS proportion directly measured from H&E-stained tissue samples, might predict GC patient survival. Applying the same computerised point counting method, we analysed another independent series of 131 GC patients from which TMAs had been constructed (LS-2, see Methods, online supplemental table 2 provides the

clinicopathological characteristics of the TMA cohort). A high ITS proportion was more commonly seen in diffuse-type GC than intestinal-type GC (median ITS diffuse-type GC: 64%, range: 17–95%; median ITS intestinal-type GC: 47%, range: 11–92%; $p=0.005$; Student's t test), in late-stage GCs than early-stage GCs (median ITS late-stage GCs: 62%, range: 11–95%; median ITS early-stage GCs: 47%, range: 13–92%; $p=0.01$), and in high-grade GCs than low-grade GCs (median ITS high-grade GCs: 57%, range: 13–95%; median ITS low-grade GCs: 47%, range: 11–82%; $p=0.007$). Similar to the genomic results, a Kaplan–Meier survival analysis comparing the one third of patients with high ITS GCs with one third of patients with low ITS GCs revealed that patients with high ITS GC had a significantly poorer prognosis ($p=0.006$, log-rank

test; figure 5E). A trend towards worsened survival was also seen in ITS high diffuse-type GCs ($p=0.29$, log-rank test). However, in multivariate analysis, including ITS proportion (continuous variable), age (<65 years vs ≥ 65 years), gender (male vs female), morphology (intestinal-type vs diffuse-type vs mixed type), grade of differentiation (well vs moderate vs poor) and pathological tumour stage according to TNM classification (UICC/AJCC 6th edition) in the Cox regression model, ITS proportion was not an independent predictor of patient survival ($p=0.682$; online supplemental table 12).

Similar to the LS-2 dataset, in the expanded SG-3 dataset, a high ITS proportion was more commonly seen in diffuse-type GCs than intestinal-type GC (median ITS diffuse-type GC: 67%, range: 15–96%; median ITS intestinal-type GC: 53%, range: 18–92%; $p=9.204 \times 10^{-5}$), in high-grade GCs than low-grade GCs (median ITS high grade GCs: 64%, range: 15–96%; median ITS low-grade GCs: 55%, range: 20–92%; $p=0.044$), and tended to be more common in late-stage GCs than early-stage GCs (median ITS late-stage GCs: 63%, range: 18–95%; median ITS early-stage GCs: 53%, range: 15–96%; $p=0.076$). Most importantly, when divided into three equal-sized groups based on their ITS proportions, SG-3 patients with high ITS GCs also exhibited a poorer overall survival compared with patients with low ITS GCs ($p=0.047$; online supplemental figure 9). The similarity of these relationships between clinicopathological data, patient survival and morphometry results compared with the genomic analysis results, both derived from entirely independent GC datasets, supports the potential existence of a biological relationship between the level of stromal super-module expression and the ITS proportion in GCs.

DISCUSSION

This study reports the largest genomic meta-analysis of GC to date exceeding previous studies by more than double the total number of patients.²² Compared with previous GC gene expression studies from single centres,^{15–20} our meta-analysis of multiple expression datasets provided increased statistical power enabling us to identify significant gene-gene relationships which would most likely be less evident in smaller datasets.²² For example, demonstrating the increased sensitivity of the current study, we were able to detect the expression of several modules related to mitochondrial and proteasomal function, which were not evident in our own previous analyses of smaller subsets of the same data.^{15–20} Previous studies based on data from a single microarray platform may also suffer from biases due to platform-specific artifacts.⁴² In contrast, our meta-analysis approach combined data from multiple independent patient populations and different microarray platforms, maximising the probability that identified relationships are biologically relevant.

Our analysis indicates that the GC coexpression network exhibits a ‘scale-free’ topological organisation where the vast majority of genes are connected to a small number of other genes (‘edges’), and only a few genes (‘hubs’) are highly connected to many other genes.^{43–45} A survey of the top ‘hub’ genes revealed involvement in normal gastric physiology (PGC, LIPF), cell adhesion (NCAM1, LGALS4, MGP), gene transcription (ILF2, H2AFZ), and signalling (PPP2R3A, PPTRC) (online supplemental table 5). It is possible that these ‘hub’ genes may function as important control nodes in the GC gene coexpression networks, however, without direct functional data the functional significance of the ‘hub’ genes in the GC coexpression network remains to be elucidated. In addition to hub genes, our analysis revealed the existence of 178 expression modules associated with diverse cellular functions ranging from cell

proliferation and immunity to mitochondrial and stromal function. Some of the identified expression modules may highlight therapeutic opportunities. For example, we observed high expression of modules related to proteasomal function in a subset of GCs. Bortezomib, a clinically approved proteasome inhibitor, has recently shown pre-clinical efficacy in GC cells.⁴⁶ It may be interesting to investigate if GCs expressing high levels of the proteasomal modules exhibit heightened sensitivity to bortezomib or other related proteasomal inhibitor compounds. We also identified relationships between modules, for example, GCs with high expression of cell proliferation modules tended to coexpress modules related to digestive function, while GCs with high expression of the stromal super-module exhibited low levels of proliferation and digestive module expression. The mutual exclusivity of the expression of the stroma and proliferation modules observed in this study is consistent with recent studies demonstrating that cancer cells can exist in either a proliferative or invasive state, but usually cannot proliferate and invade at the same time.^{47–49}

We found that the expression level of a TGF- β associated super-module of stroma-related genes consistently predicted clinical outcome in multiple independent GC datasets. Expression of the stromal super-module was also related to the ITS proportion, a specific morphological GC phenotype and diffuse-type histology. These genomic and morphometric results are of clinical relevance, as they suggest that the prognosis of GC patients may be influenced by cancer cells and by other cell types residing in the tumour stroma. Our results also provide a molecular basis that may explain, at least in part, the poor prognosis of diffuse-type GC patients. First, the negative correlation between stroma and cell proliferation may contribute to the poor response of diffuse-type GCs to cytotoxic chemotherapy, which targets actively dividing cells. Second, a high ITS proportion may directly inhibit the effects of current therapies by reducing both drug delivery to tumour cells^{50,51} and protecting cells against chemotherapy-induced apoptosis.⁵² Third, recent functional studies have indicated that the tumour stroma may play a vital role in the differentiation, proliferation and migration of tumour cells,⁵³ and the tumor stroma may contribute to aggressive disease by providing a favourable mechano-environmental scaffold necessary for tumour progression.⁵⁴ These findings are supported by studies in different cancer types including oesophageal,⁵⁵ colorectal,^{39,56} prostate,⁵⁷ pancreatic,⁵⁸ breast and liver cancers,⁵⁹ which showed that the tumour microenvironment and stroma may play significant roles in patient prognosis and chemosensitivity.^{60–63} However, to our knowledge, our report is the first to demonstrate a prognostic role of the tumour stroma in GC, highlighting the potential role of the ITS proportion as a predictive biomarker to identify subgroups of patients with GCs that might respond to therapies directed towards the tumour stroma.

Given the association between stromal super-module expression levels and GC patient survival, and the current limited impact of targeted agents (trastuzumab, lapatinib) in diffuse-type GCs, we were interested in identifying the molecular pathways potentially influencing intra-tumoural stroma growth. By correlating the expression levels of the stromal super-module to the activity of different oncogenic-signalling pathways, our analysis strongly implicates the TGF- β signalling pathway as a key regulator of the intra-tumoural stroma. Although the TGF- β pathway has been historically viewed as a tumour-suppressive pathway where tumour cells often exhibit mutational or epigenetic inactivation of TGF- β pathway components, such as TGF β RI, TGF β RII and SMAD4,⁶⁴ recently published work

suggests that TGF- β signalling in tumours is more complex and may stimulate a pro-tumourigenic stromal environment.⁶⁵ For example, TGF- β ligands secreted by cancer cells have been shown to alter the function of healthy fibroblasts within the tumour stroma, leading to a myofibroblast-like phenotype supporting tumour growth, vascularisation and metastasis.^{66 67} Notably, the TGF- β pathway has been identified as a target for therapeutic intervention using endogenous proteins, such as soluble betaglycan or decorin, or artificial agents, such as anti-sense oligonucleotides, antibodies or small-drug molecules.⁶⁴ Given the dearth of therapeutic options for GC patients at present, it will be important to assess if targeting TGF- β might prove an effective strategy for perturbing the GC tumour stroma and improving patient outcomes.

In summary, this is the first comprehensive genomic meta-analysis of GC transcriptome data, generating a robust inventory of multiple gene-expression modules present in GCs. Our analysis revealed that the level of stromal super-module expression in GCs may serve as a novel prognostic factor in GC, and that this pathway is likely to involve TGF- β signalling. Admittedly, the association between patient survival and stromal gene expression/ITS proportion, while statistically significant, is relatively weak with regard to effect size. As such, it remains currently uncertain whether measuring the ITS proportion will prove to be a useful clinical tool for predicting GC patient prognosis, above and beyond the accepted standard of TNM tumour staging. To definitively address this question, future research goals will involve measuring the ITS proportion in patient materials from large prospective multicentre randomised controlled trial populations, where potential biases, due to disease stage, patient-related factors, treatment, pathology reporting and tissue collection are minimised. Finally, very few of our patients received chemotherapy prior to surgery, and hence, our results cannot address the prognostic value of the ITS proportion after neoadjuvant chemotherapy. Given the increasing use of neoadjuvant chemotherapy in GC patients in the West,^{68 69} it will be intriguing to evaluate the impact of neo-adjuvant chemotherapy on ITS at the histological and molecular level.

Inventory of Supplemental Data:

Supplemental Figures 1-12

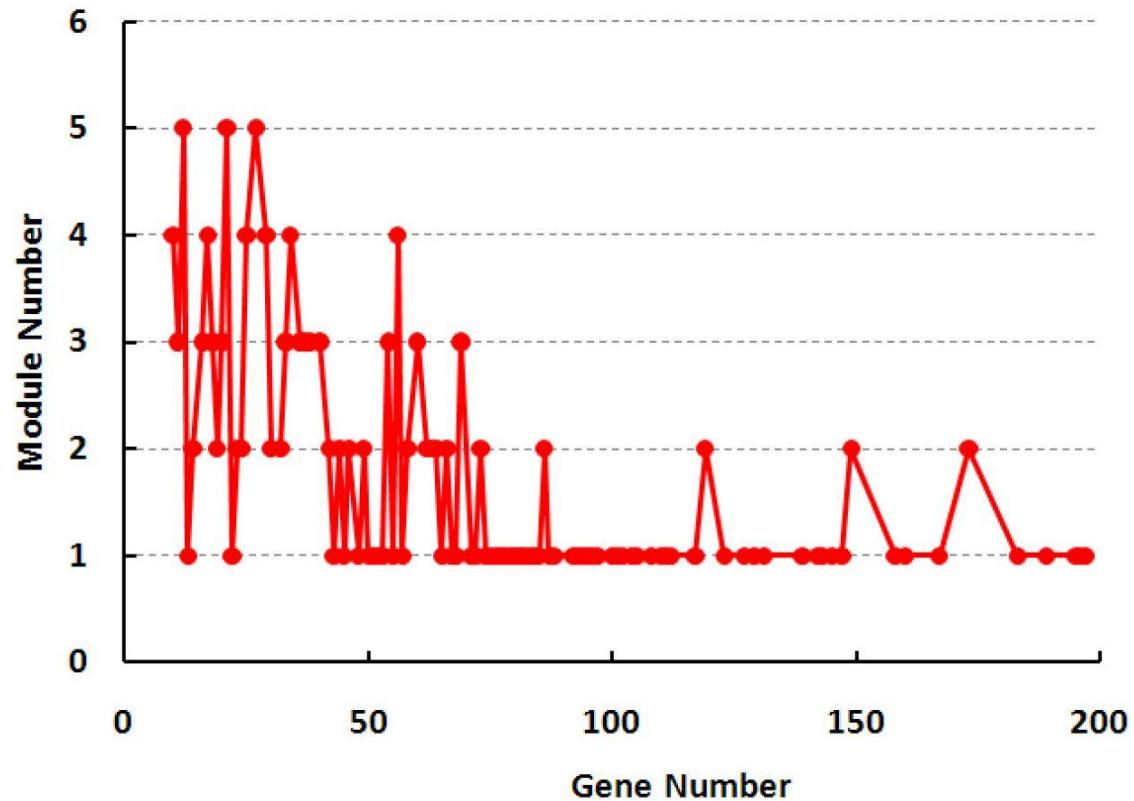

Supplemental Tables 1-13

Supplemental Methods

Supplemental References

Supplemental Documents 1-3

Supplemental Figure 1

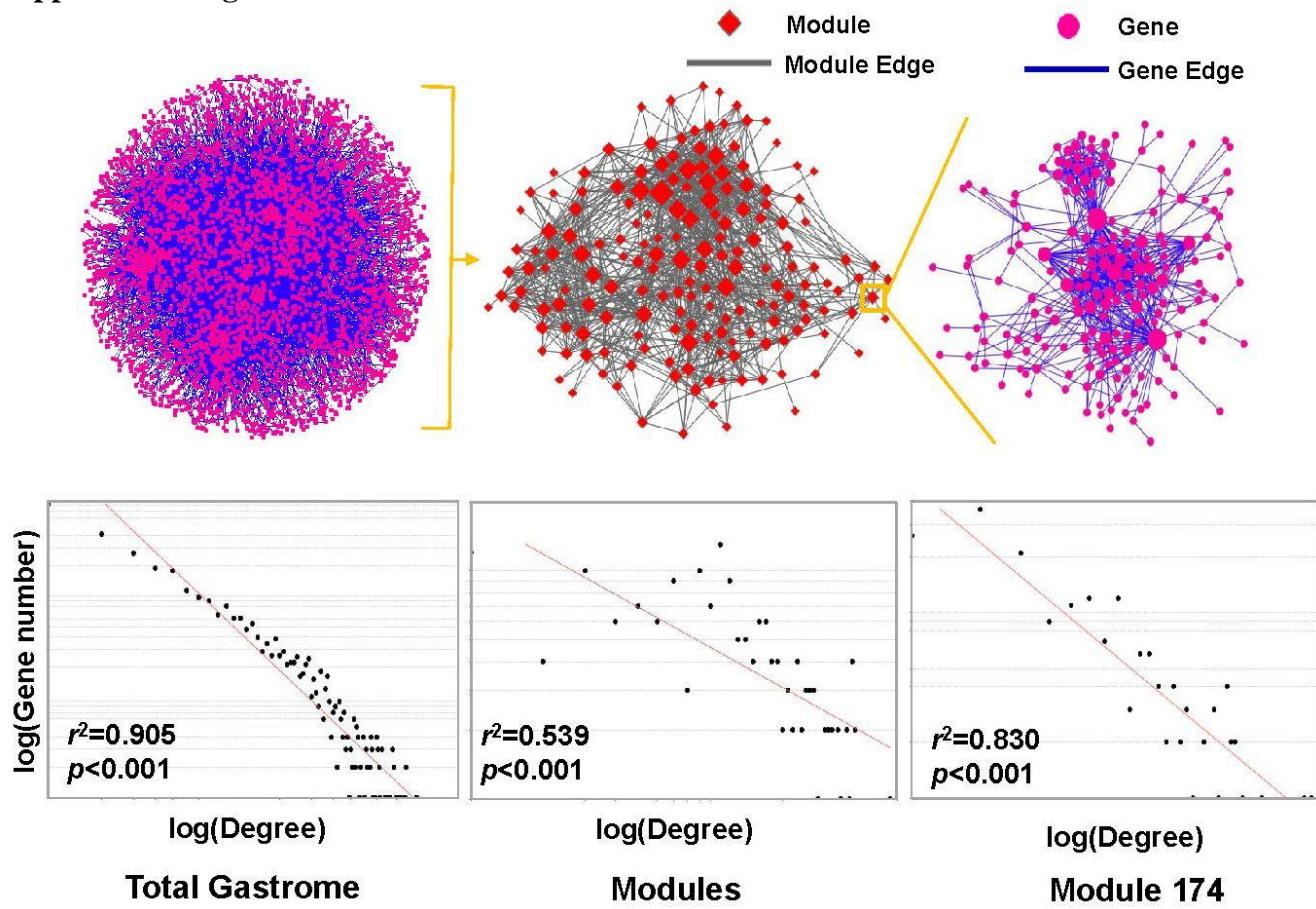

Supplemental Figure 1. Numbers of genes in modules.

Shown are the numbers of genes associated with different modules. All 178 modules were considered.

The average number of modules associated with any given gene was 4.17.

Supplemental Figure 2

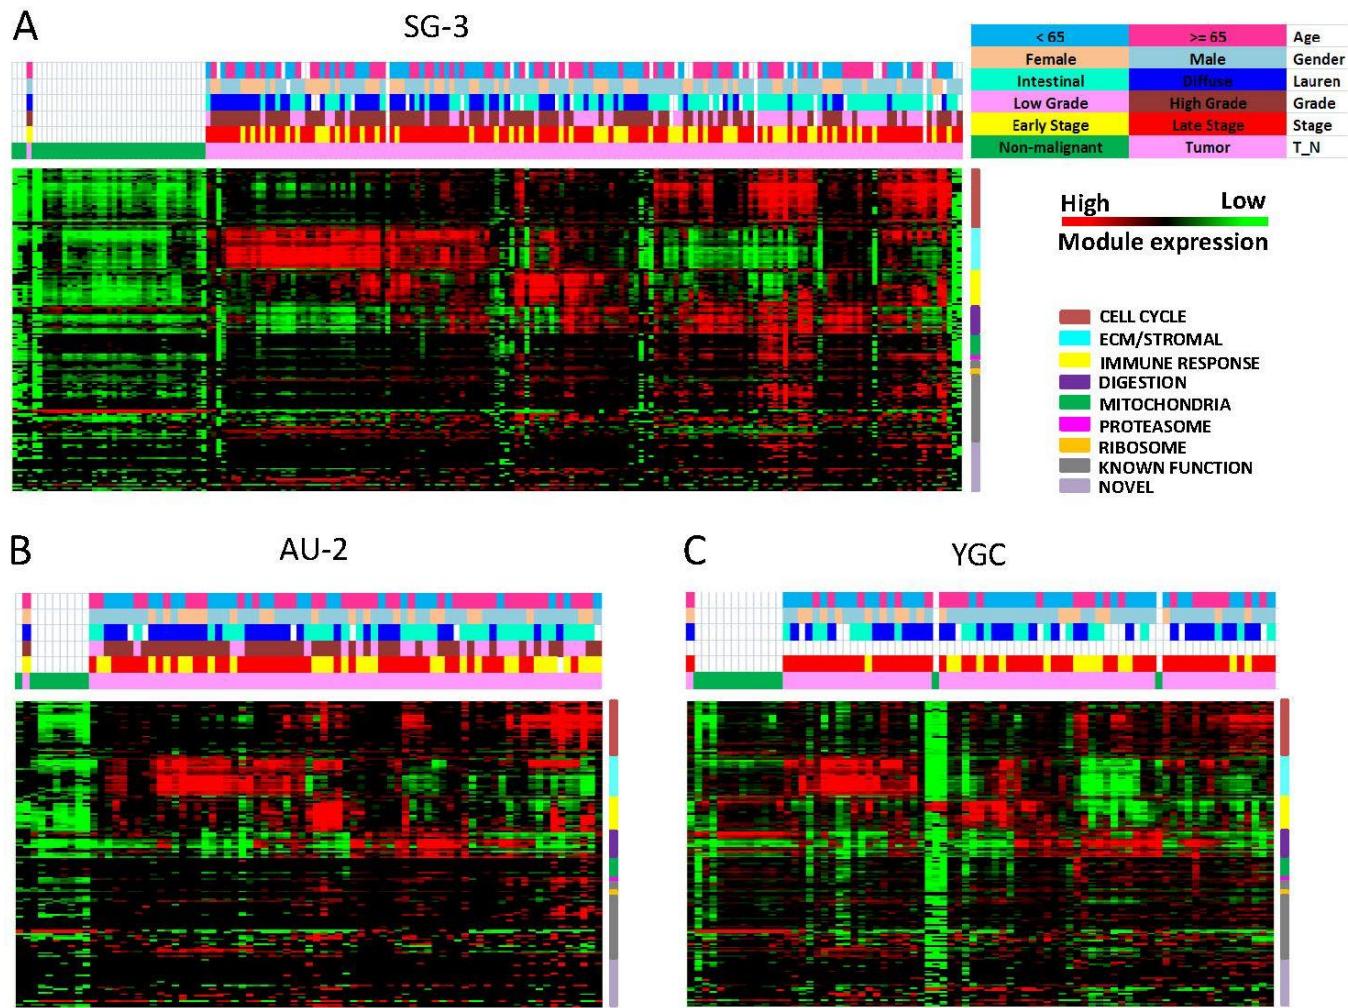

Supplemental Figure 2. Topological properties of the gastric coexpression network.

The three panels (left, middle, right) represent the gastric coexpression network visualized at different levels. The top three network diagrams depict the distinct network organization being analyzed. (left, top) A network diagram of all genes and edges in the coexpression network. Pink circles represent gene nodes connected by edges (blue lines), and sizes of the pink circles reflect the number of edges connected to the node. (middle, top) A network diagram of all modules in the coexpression network. Red diamonds depict individual modules and grey lines represent module edges linking modules exhibiting significant degrees of similarity (minimum $p < 10^{-5}$, hypergeometric test). Sizes of diamonds reflect the number of edges linked to each module. (right, top) A network diagram of genes found in a single module. The color code is the same as used for the left network diagram. The bottom graphs show the relationships between the network nodes and the number of edges associated with each node. The y - axis represents the number of nodes (y - axis, log scale) while the x - axis represents the ‘node degree’ which is the number of edges linked to each node (x - axis, log scale). In each of the three networks, the

distribution of node-edge connections was found to obey a power-law relationship. Here, $p < 0.001$ indicates that the actual r^2 correlation exceeds the maximal r^2 value when the x - axis values were randomly permuted 1000 times.

Supplemental Figure 3

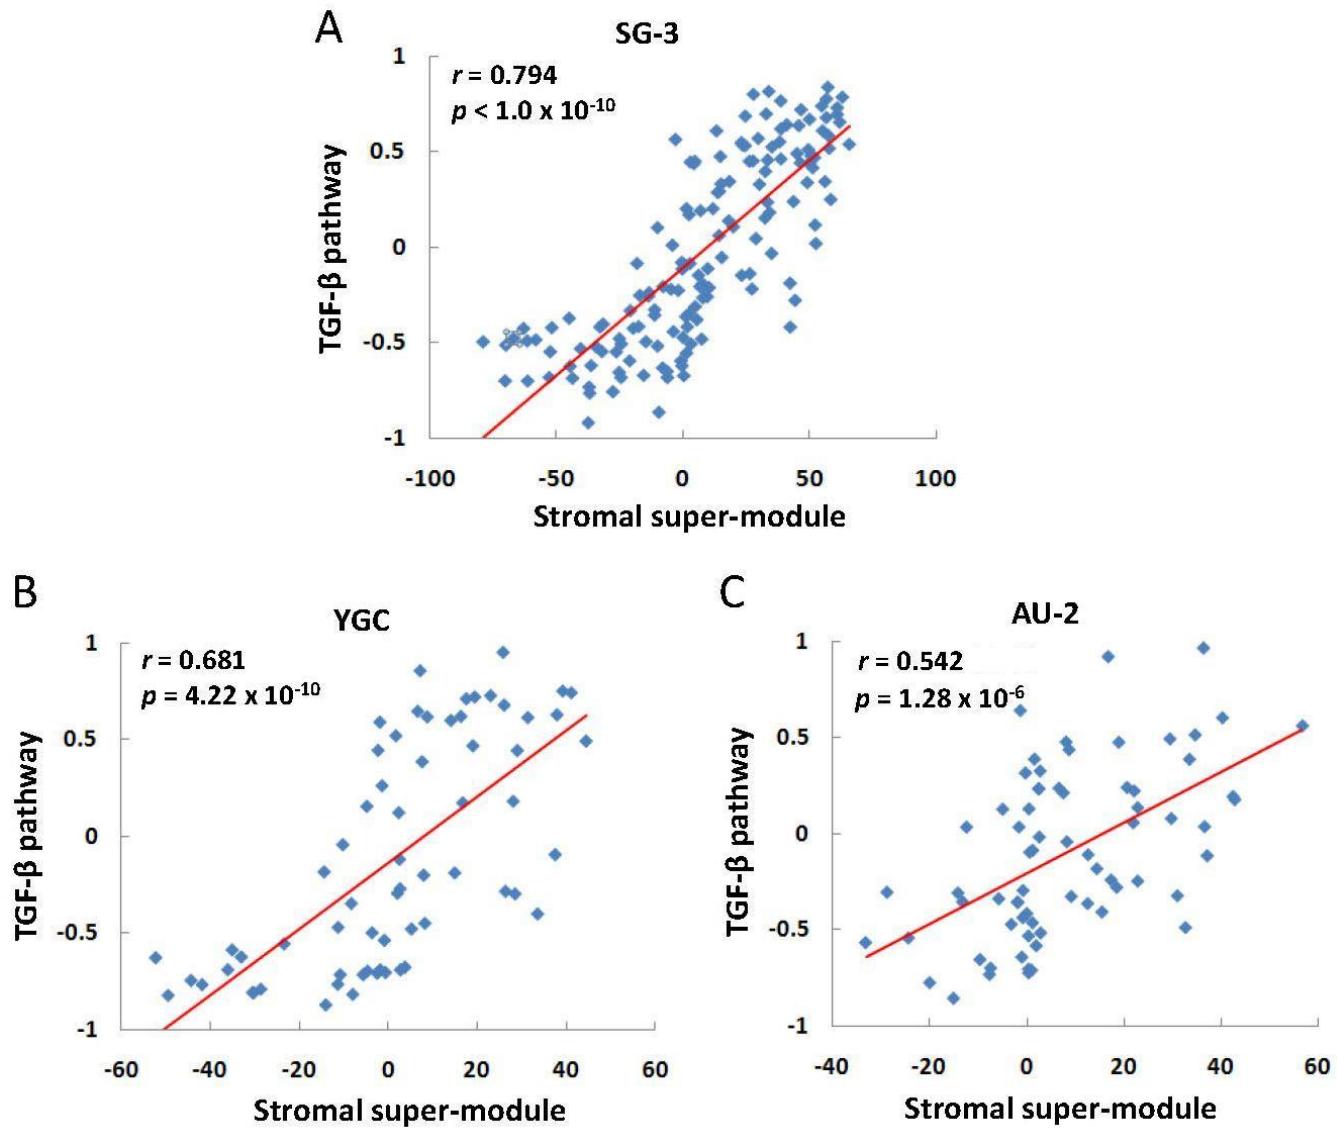

Supplemental Figure 3. Patterns of module expression associated with distinct molecular and histopathological features in three validation datasets (SG-3, AU-2 and YGC).

Heat maps showing different combinations of module expression in three independent validation datasets: (A) SG-3 (153 GCs and 38 non-malignant gastric tissues), (B) AU-2 (70 GCs and 9 non-malignant gastric tissues), (C) YGC (65 GCs and 14 non-malignant gastric tissues). Within each heat map, columns represent individual samples, and rows represent expression levels of the individual modules. Red represents modules that are highly expressed, while green represents modules expressed at low levels. The vertical color bar to the right of the heat maps represents the super-modules (see color code). Colored bars above the heat map represent different clinicopathological features (age (< or ≥65

years), gender, Laurén classification, grade of differentiation, stage and tissue type (cancer or non-malignant) (color legend on top right).

Supplemental Figure 4

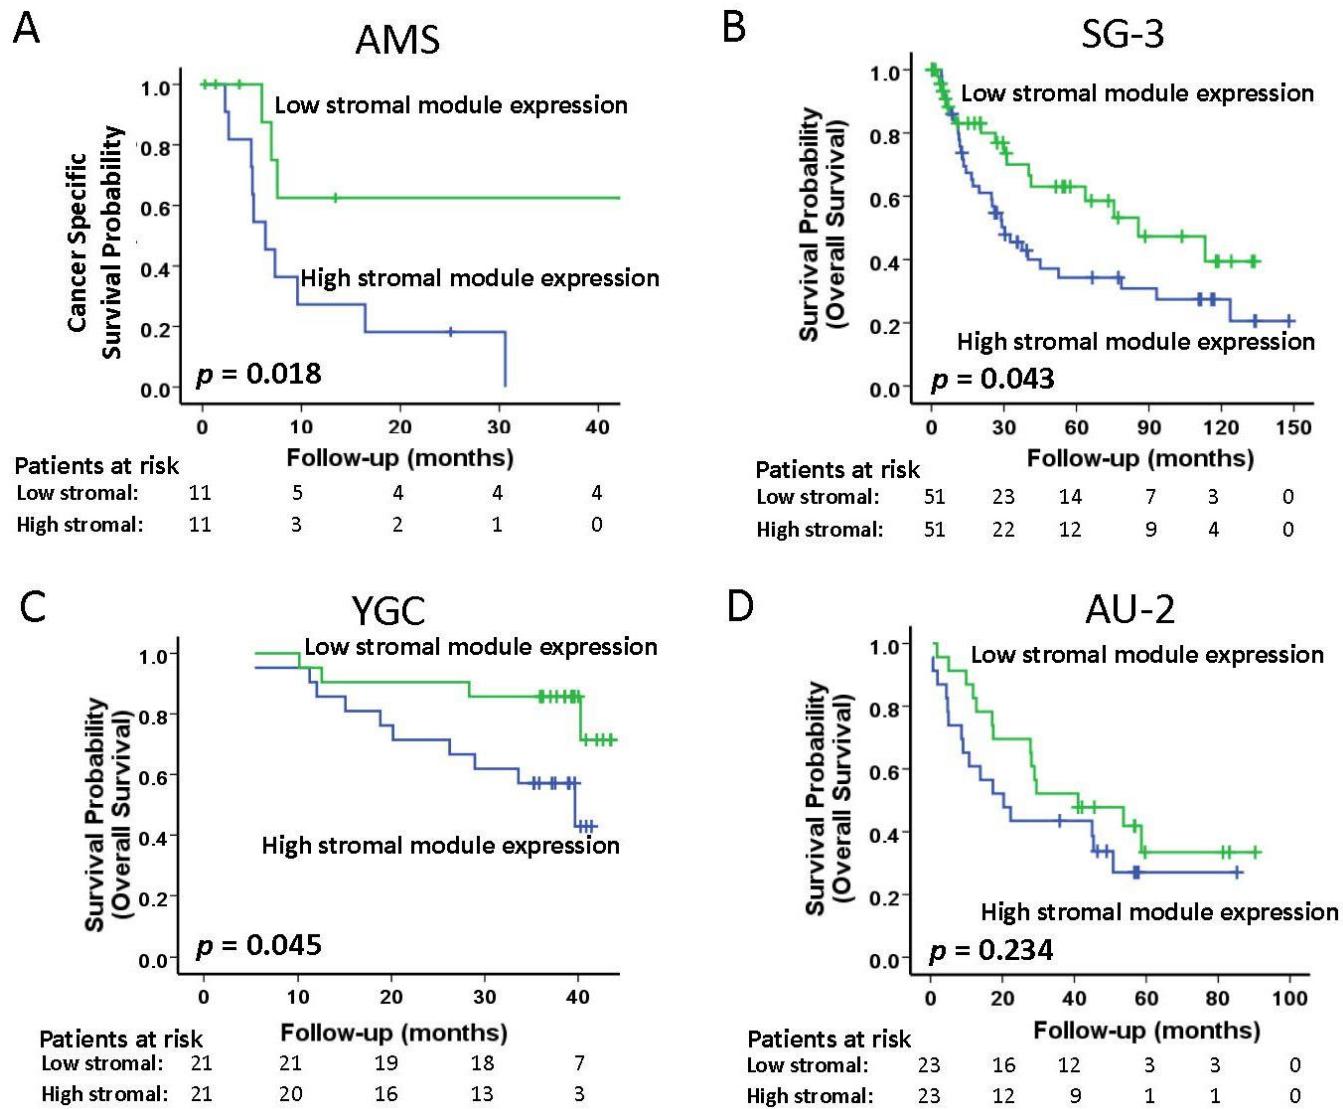

Supplemental Figure 4. Relationship between stromal super-module expression and TGF- β signaling in three validation datasets (SG-3, AU-2 and YGC).

The y - axis represents levels of TGF- β pathway activation, while the x - axis represents levels of stromal super-module expression. Each point depicts an independent cancer sample.

(A) SG-3 ($n = 153$ GCs). The correlation coefficient between TGF- β pathway activation and stromal super-module expression was $r = 0.794$, $p < 1.0 \times 10^{-323}$. (B) YGC ($n = 65$ GCs). The correlation coefficient between TGF- β pathway activation and stromal super-module expression was $r = 0.681$, $p =$

4.22×10^{-10} . (C) AU-2 ($n = 70$ GCs). The correlation coefficient between TGF- β pathway activation and stromal super-module expression was $r = 0.542$, $p = 1.28 \times 10^{-6}$.

Supplemental Figure 5

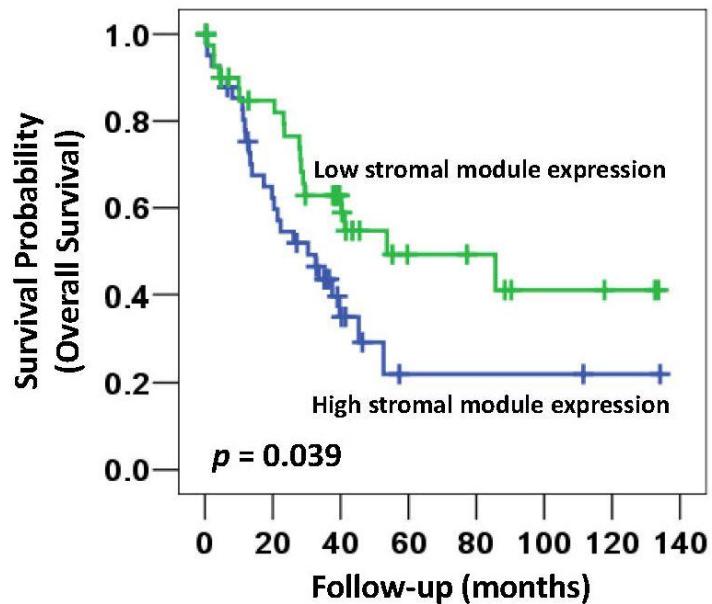

Supplemental Figure 5. Expression of the stromal super-module predicts patient prognosis in four validation datasets (AMS, SG-3, AU-2, YGC).

(A) Survival analysis using the AMS dataset (34 GC). Kaplan-Meier survival analysis demonstrated that patients with GC exhibiting high levels of stromal super-module expression had poorer survival than patients with GC exhibiting low levels of stromal super-module expression ($p = 0.018$). (B) Survival analysis of the SG-3 dataset (153 GCs). Kaplan-Meier survival analysis demonstrates that patients with GC exhibiting high levels of stromal super-module expression have poorer survival than patients with

GC exhibiting low levels of stromal super-module expression ($p = 0.043$). **(C)** Survival analysis using the YGC dataset (65 GC). Kaplan-Meier survival analysis demonstrates that patients with GCs exhibiting high stromal super-module expression had poorer survival than patients with GC exhibiting low levels of stromal super-module expression ($p = 0.045$). **(D)** Survival analysis using the AU-2 dataset (70 GC). Kaplan-Meier survival analysis demonstrated that patients with GC exhibiting high levels of stromal super-module expression had poorer survival than patients with GC exhibiting low levels of stromal super-module expression ($p = 0.234$).

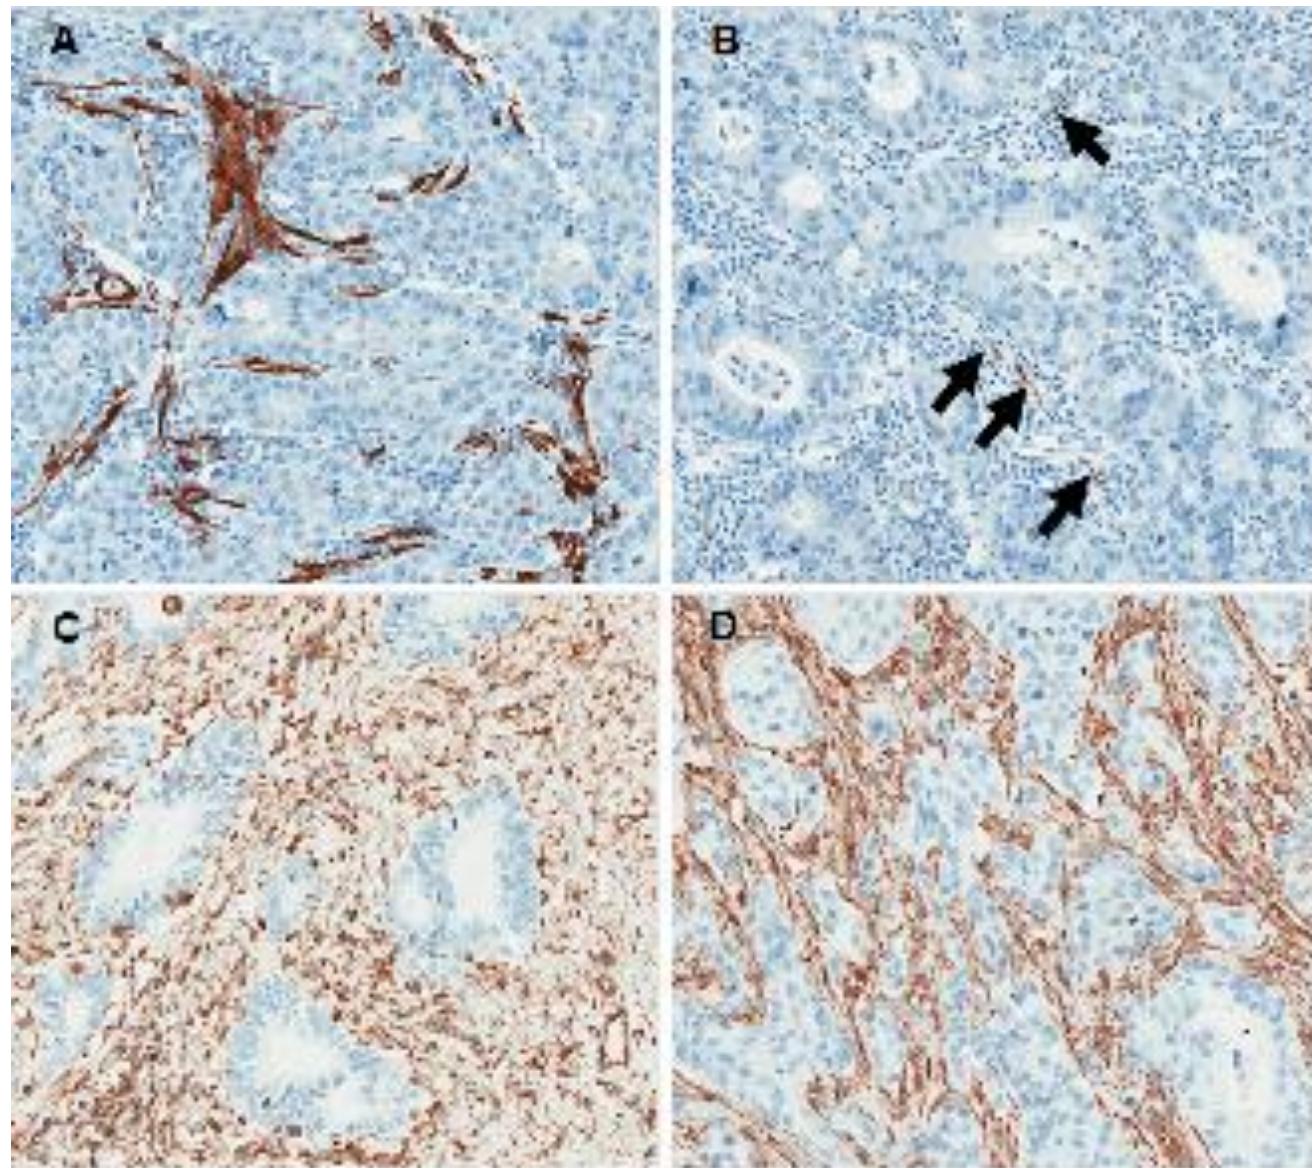

Supplemental Figure 6

Supplemental Figure 6. Stromal super-module expression predicts Stage III patient prognosis in the combined validation dataset.

Stage III patients were divided into three equally sized groups based on levels of stromal super-module expression – high stroma (top 1/3), moderate stroma (middle 1/3), and low stroma (bottom 1/3). Kaplan-Meier analysis was used to compare overall survival probability from the time of surgery of patients with either high stroma (top 1/3) or low stroma (bottom 1/3) GC. Stage III GC patients with high stroma GC had a poorer prognosis ($p = 0.039$).

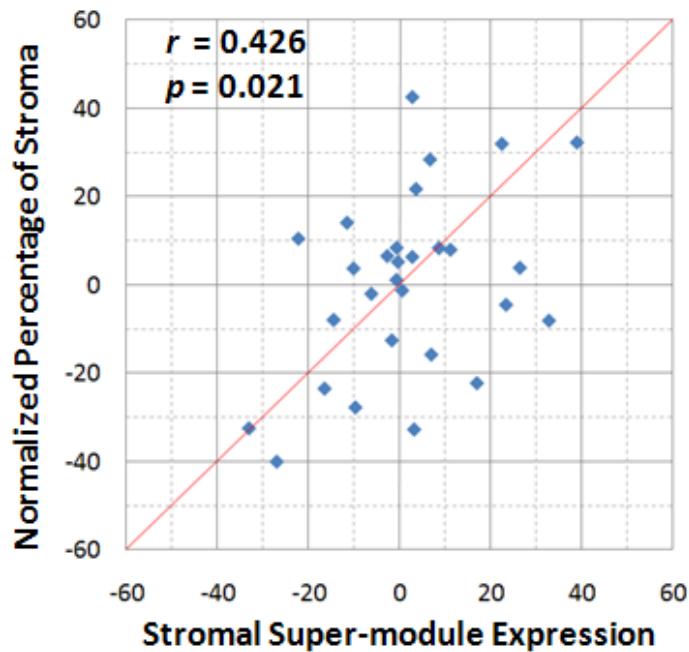

Supplemental Figure 7

Supplemental Figure 7. Caldesmon and vimentin expression in GC

Full sections of 29 GCs were subjected to immunohistochemistry (chromogen: DAB, counterstain: haematoxylin; 20x magnification used in all images). Caldesmon positivity in the stroma is a rare in GC. (A) Relative large amount of caldesmon positive stroma between tumour glands. (B) Very small amount of caldesmon positive stroma (see arrows). Vimentin positive stroma is much more abundant in GC compared to caldesmon. (C) Tumour glands are separated from each other by large amount of vimentin positive stroma. (D) Tumour glands are separated from each other by small amounts of vimentin positive stroma.

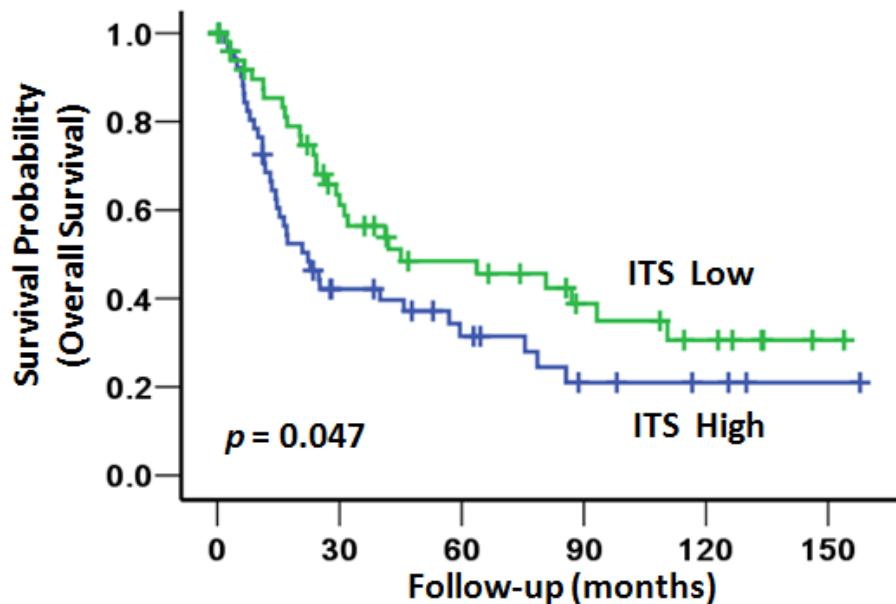

Supplemental Figure 8

Supplemental Figure 8. Association of stromal super-module expression with the ITS proportion in the LS-1 dataset.

The y - axis represents the normalized ITS proportion measured by morphometry (see Methods). The x - axis represents the expression level of the stromal super-module. Each point represents an individual GC. A significant positive correlation was observed (correlation coefficient $r = 0.426$, $p = 0.021$).

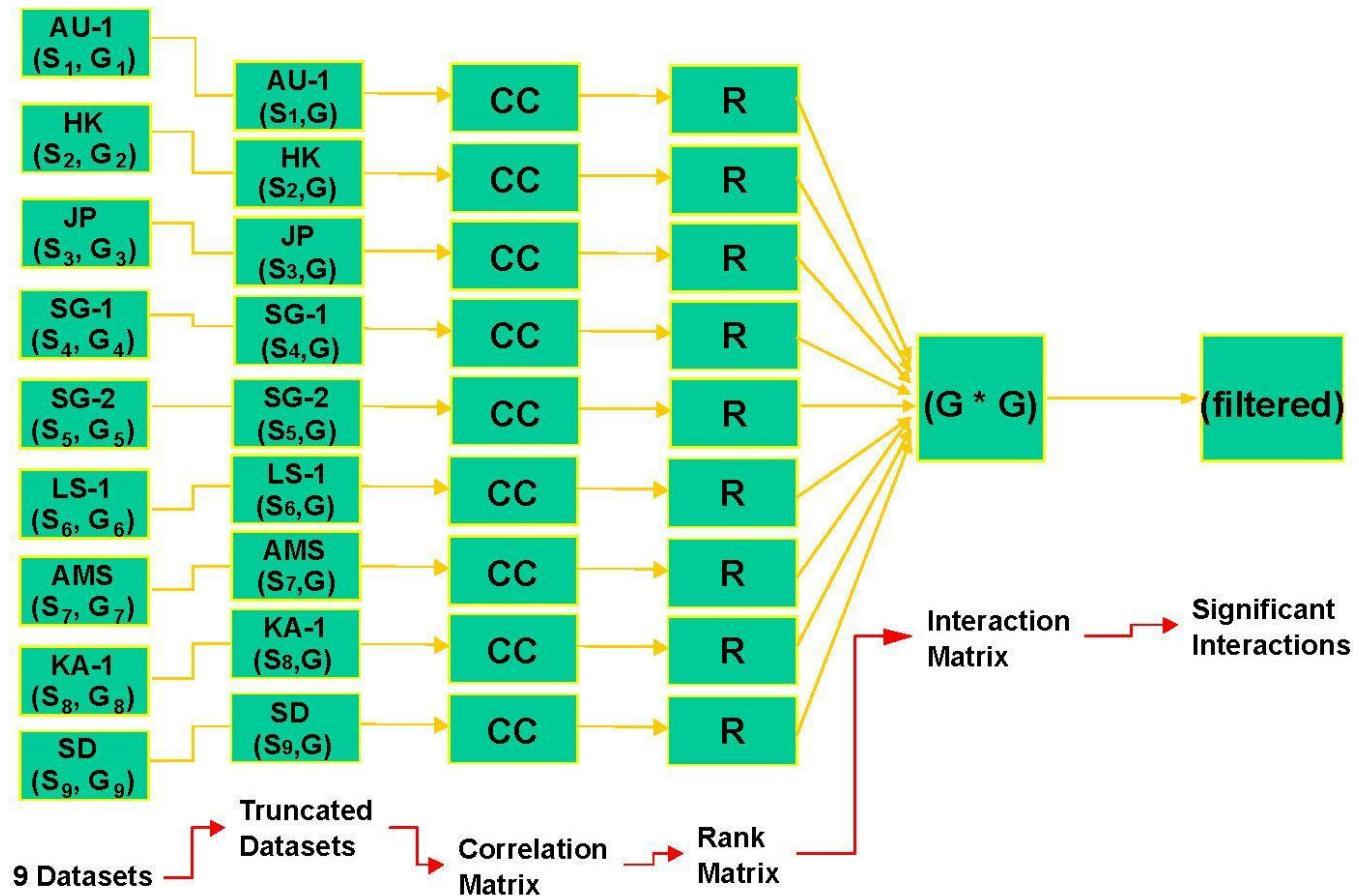

Supplemental Figure 9

Supplemental Figure 9. The ITS proportion predicts patient prognosis (SG-3 dataset)

156 GCs in SG-3 dataset were divided into three equal sized groups based on the levels of ITS – GCs with high ITS proportion, GCs with moderate ITS proportion, and GCs with low ITS proportion. Kaplan-Meier analysis demonstrates that patients with GCs exhibiting a high ITS proportion (blue line) have poorer cancer specific survival compared to patients with low ITS proportion GCs (green line, $p = 0.047$).

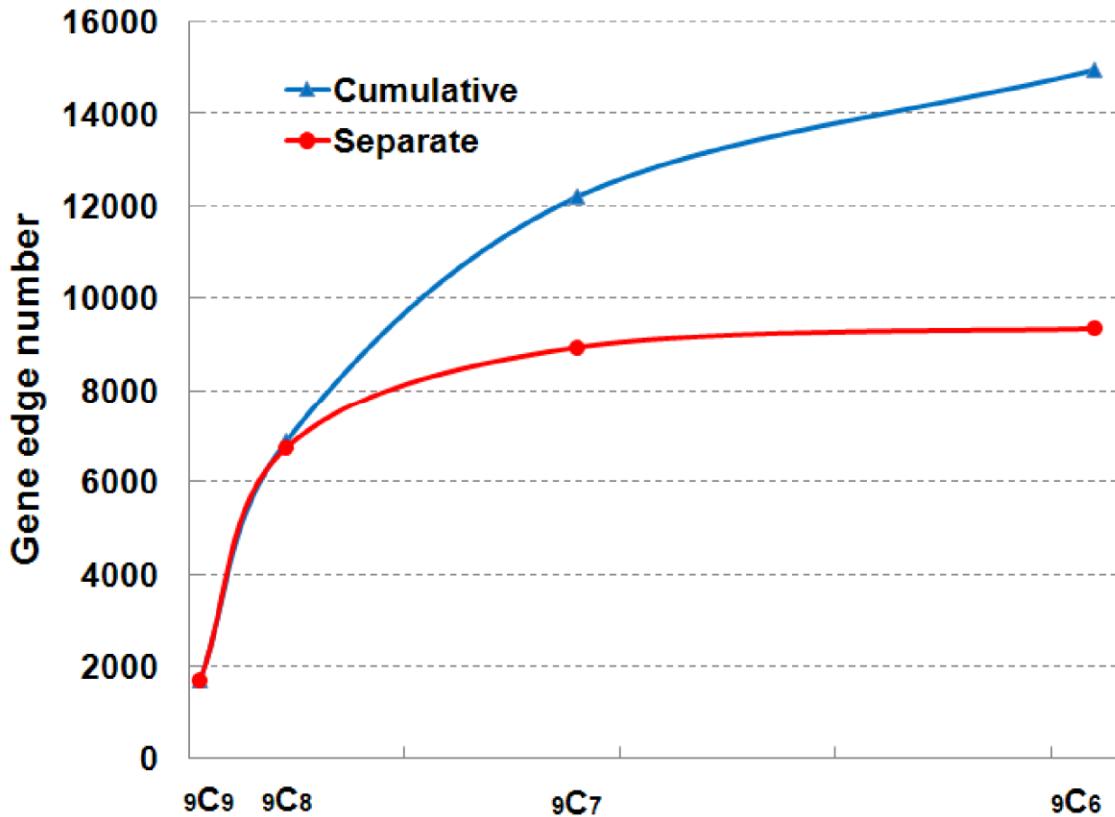

Supplemental Figure 10

Supplemental Figure 10. Schematic of GC network construction.

Microarray data from nine GC datasets (AU-1 to SD) were individually mapped to a common Unigene platform (G, UniGene Cluster Annotation ID Build No. 194, Released 2006-08-02). Pearson's correlation coefficients were calculated for every gene-gene pair to construct correlation matrices (CC), which were subsequently converted to a ranked matrix (R). Rank-statistics were used to evaluate the consistency of ranks for each gene pair creating a $G \times G$ interaction matrix. On the basis of their *FDR* (False Discovery Rate) values, an *LLR* (Log-Likelihood Ratio) cut-off was used to identify significant interactions. An in-depth description of the network construction method is presented in Aggarwal *et al.*, 2006.

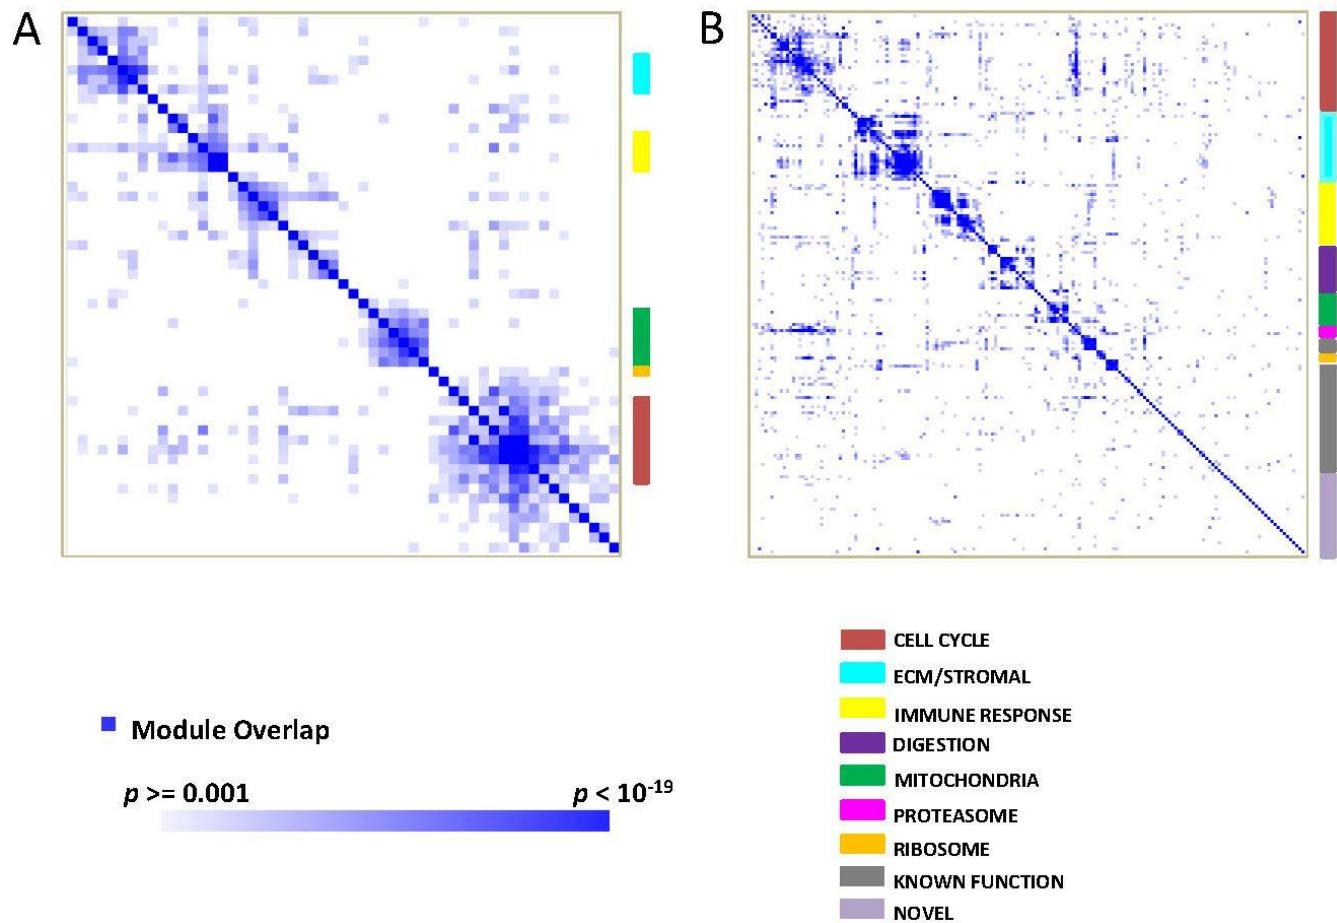

Supplemental Figure 11

Supplemental Figure 11. Rate of discovery of novel edges with additional data combinations.

The red line represents the non-cumulative number of edges found in each independent dataset combination (${}^9\text{C}_9$ to ${}^9\text{C}_6$). The blue line represents the cumulative increase in new edges. The rate of discovery of new edges gradually decreases from ${}^9\text{C}_9$ to ${}^9\text{C}_6$.

Supplemental Figure 12

Supplemental Figure 12. Co-expression modules in the Core and Expanded GC Networks

The white-blue heat map presents overlaps in gene composition overlap between a) the 666-gene core network (55 modules) and b) the 3177-gene expanded network (178 modules, taken from Figure 1B in the Main Text). Darker blue regions represent modules with significant gene overlap. The white-blue scale bar indicates p-values for the module overlap (hypergeometric test). The multicolored vertical color bar to the right of the white-blue heat map represents groups of modules exhibiting significant overlap in gene content (super-modules, see color code at bottom right). Modules such as the digestive module and the proteosomal module are not observed in the 666-gene core network, but are evident in the expanded network.

Supplemental Table 1. List of GC datasets used in this study.

Dataset	Research Center	Platform	#Features	#Sample	#Non-malignant (matched to GC)	#Tumor	Unique Unigenes	Pubmed ID/Source
AU-1	Peter MacCullum, Cancer Center, Australia	Custom cDNA	10.5k	124	59(100%)	65	6404	12750281 (GSE2669)

Total				591	163(63.19%)	428	31096	

Nine datasets of GC patients were analyzed by expression profiling at the Peter MacCullum Cancer Centre (Australia), Queen Mary Hospital, The University of Hong Kong (Hong Kong), RCAST University of Tokyo (Japan), National Cancer Centre (Singapore), Leeds Institute for Molecular Medicine, St James's University Hospital (Leeds), VU University Medical Centre Amsterdam (Amsterdam), Human Genomics Laboratory, Genome Research Center, Korea Research Institute of Bioscience and Biotechnology (Korea), and Departments of Health Research and Policy, Stanford University (Stanford). Each dataset was preprocessed by the individual research centers, and normalized data deposited at a central server at Duke-NUS Graduate Medical School. Multiple probes mapping to same UniGene were averaged after a \log_2 transformation. GC = Gastric Cancer, CG = Chronic Gastritis, IM = Intestinal Metaplasia. See Aggarwal *et al.*, 2006 for details.

Supplemental Table 2. Clinicopathological characteristics of the Gastric Cancer LS-2 dataset used for ITS measurements by point counting of H&E stained tissue microarray cores.

Clinicopathological characteristics	Category	LS-2
Age (years)	median (range)	68 (24 to 86)
	N (%)	
Gender	Male	81 (62)
	Female	50 (38)
UICC/AJCC Stage+	I	60 (46)
	II	29 (22)
	III	41 (32)
	unkown	1
Laurén classification	Intestinal	91 (69)
	Diffuse	30 (23)
	Mixed	10 (8)
Grade of Differentiation+	Well	17 (13)
	Moderate	45 (35)
	Poor	68 (52)
	Unkown	1

Supplemental Table 3. Comparison of the current GC network to Aggarwal et al., 2006

Network	Nodes	Edges		FDR
GC Network (2012)	3177	14965		<0.001
		Positive	Negative	
		11447	3518	
GC Network (2012)	6359	95855		<0.01
		Positive	Negative	
		56037	39818	
GC Network (2006)	588	925		<0.016

The total numbers of nodes and edges in the current GC network are listed at two levels of sensitivity (*FDR* < 0.001 or < 0.01) in the first two rows. In comparison to the original GC network reported in Aggarwal *et al.*, 2006 (3rd row), the current GC network had more than 10x the number of genes (nodes) and more than 100x the number of edges (eg 6359 vs. 588 for nodes and 95855 vs. 925 for edges) at similar levels of sensitivity (< 0.01 vs < 0.016). 558 (95%) of 588 genes originally identified in the 2006 GC network were also found in the current GC network (*FDR* < 0.01). 741 (80%) of 925 edges in the 2006 GC network were also found in the current GC network (*FDR* < 0.01).

Supplemental Table 4. Molecular composition of module 4. Module 4 was enriched in genes related to chromosomal region chr19p13.

Gene Name	Gene Annotation	Chromosomal Position	Pathway	TF binding site	GO
FARS1A	Phenylalanine-tRNA synthetase-like, alpha subunit	chr19p13	SERUM FIBROBLAST CORE UP; BRCA1 OVEREXP DN; MYC ONCOGENIC SIGNATURE	GGAANCGGAANY UNKNOWN

RABGAP1L	RAB GTPase activating protein 1-like	chr1q24	FERNANDEZ MYC TARGETS; FALT BCCL DN; UVC TTD ALL DN;		

Supplemental Document 1 provides all the member genes of the 178 modules and Supplemental Document 2 provides a comprehensive table of the 178 modules and their MSigDB assignments.

Supplemental Table 5. Top 20 hub genes in the current GC Network (*FDR* < 0.001)

Gene Symbol	Gene Title	Degree*
PGC	Progastricsin (pepsinogen C)	117
C9orf61	Chromosome 9 open reading frame 61	102
ADH1C	Alcohol dehydrogenase 1C (class I), gamma polypeptide	102
DGKD	Diacylglycerol kinase, delta 130kDa	101
SULT1C1	Sulfotransferase family, cytosolic, 1C, member 1	100
CTSE	Cathepsin E	95
LIPF	Lipase, gastric	94
NCAM1	Neural cell adhesion molecule 1	91
LGALS4	Lectin, galactoside-binding, soluble, 4 (galectin 4)	90
PCNA	Proliferating cell nuclear antigen	87
TUBB	Tubulin, beta	87
ILF2	Interleukin enhancer binding factor 2, 45kDa	86
CCL19	Chemokine (C-C motif) ligand 19	86
LGALS3	Lectin, galactoside-binding, soluble, 3 (galectin 3)	86
C1QB	Complement component 1, q subcomponent, B chain	83
MGP	Matrix Gla protein	82
UBE2C	Ubiquitin-conjugating enzyme E2C	81
PPP2R3A	Protein phosphatase 2 (formerly 2A), regulatory subunit B'', alpha	80
H2AFZ	H2A histone family, member Z	78
PTPRC	Protein tyrosine phosphatase, receptor type, C	75

* the degree of a node gene in a GC network is the number of connections it has with other node genes

Supplemental Table 6. GC expression modules significantly associated with distinct clinicopathologic characteristics in the combined validation series. All *p*-values have been corrected for multiple hypotheses, *p*-value < 0.05.

	Age		Gender		UICC/AJCC stage		Laurén classification		Grade of differentiation	
	<65 yr	≥65 yr	Male	Female	Early stage	Late stage	Intestinal	Diffuse	Low grade	High grade
Cell cycle		1.47×10^{-7}	$<1.00 \times 10^{-323}$		4.32×10^{-9}		$<1.00 \times 10^{-323}$		$<1.00 \times 10^{-323}$	
ECM/Stromal	$<1.00 \times 10^{-323}$			$<1.00 \times 10^{-323}$		$<1.00 \times 10^{-323}$		$<1.00 \times 10^{-323}$		$<1.00 \times 10^{-323}$
Immune response	6.69×10^{-3}						3.45×10^{-3}			1.08×10^{-5}
Digestion							6.97×10^{-13}		$<1.00 \times 10^{-323}$	
Mitochondria		4.99×10^{-3}			7.68×10^{-9}		3.0×10^{-3}		2.93×10^{-9}	
Proteasome			9.1×10^{-4}		0.035		4.95×10^{-14}		5.49×10^{-7}	
Ribosome		0.028			5.87×10^{-3}					

Numbers in the boxes highlight those associations between levels of super-module expression and clinicopathologic characteristics found to be significant (corrected *p* < 0.05). See the Main Text for the directionalities of the associations.

Supplemental Table 7. GC expression modules associated with distinct clinicopathologic characteristics in individual validation datasets. All *p*-values have been corrected for multiple hypotheses, *p*-value < 0.05.

	Age		Gender		UICC/AJCC stage		Laurén Classification		Grade of differentiation	
	<65 yr	≥65 yr	Male	Female	Early stage	Late stage	Intestine	Diffuse	Low grade	High grade
Cell cycle		2.26*10 ⁻⁵ (YGC); 0.025 (AU-2)	2.76*10 ⁻⁹ (SG-3); 2.61*10 ⁻⁵ (YGC); 0.001 (AU-2)		<1.00*10 ⁻³²³ (YGC); 2.22*10 ⁻⁷ (AU-2)		<1.00*10 ⁻³²³ (SG-3); <1.00*10 ⁻³²³ (AU-2)	<u>1*10⁻⁴</u> (YGC)	<1.00*10 ⁻³²³ (SG-3); 5.76*10 ⁻⁷ (AU-2)

Ribosome										

Numbers in the boxes those associations between levels of super-module expression and clinicopathologic characteristics found to be significant in the individual validation sets (corrected $p < 0.05$). Set names are, SG-3, AU-2, and YGC. Of the 69 associations found to be significant in the 349-combined validation set, 61 exhibited a similar trend in all individual datasets, and only 8 associations (bold type) exhibited an opposite trend in at least one individual dataset. Among these 8, only one value in (bold type and underlined; Lauren classification, YGC) exhibited a significant ($p < 0.05$) opposite trend to those observed in the 349-sample set.

Supplemental Table 8. GC expression modules were associated with distinct oncogenic pathways in the combined validation series. All *p*-values have been corrected for multiple hypotheses, *p*-value < 0.05.

III + IV	189	0.024	0.009	1.009 (1.001 to 1.016)
I + II + III + IV	284	0.023	0.007	1.007 (1.001 to 1.013)

* Stromal module expression was treated as a continuous variable.

Supplemental Table 12. Cox regression analysis of intratumoral stroma (ITS) and other clinical variables in the LS-2 dataset (131 GC patients).

Covariate	Univariate			Multivariate	
		HR (95.0% CI)	P	HR (95.0% CI)	P
ITS	Continuous Variable	1.017 (1.003 to 1.032)	0.019	1.003 (0.988 to 1.018)	0.682
Age	< 65 years	1		-	-
	≥ 65 years	0.987 (0.562 to 1.734)	0.963*	-	-
Gender	Female	1		-	-
	Male	0.644 (0.368 to 1.130)	0.125	-	-
UICC staging	I	1		1	
	II	1.393 (0.539 to 3.595)	0.494	1.413 (0.540 to 3.696)	0.481
	III	7.178 (3.568 to 14.44)	< 0.001	7.379 (3.534 to 15.408)	< 0.001
Morphology type	Intestinal	1		1	
	Diffuse	2.312 (1.265 to 4.225)	0.006	2.431 (1.1151 to 5.299)	0.025
	Mixed	0.923 (0.281 to 3.032)	0.895	0.655 (0.177 to 2.420)	0.526
Grade	G1	1		1	
	G2	2.430 (0.707 to 8.346)	0.158	1.396 (0.400 to 4.879)	0.601
	G3	3.432 (1.047 to 11.26)	0.042	1.530 (0.419 to 5.591)	0.52

* Age is not significantly associated with cancer-specific survival ($p = 0.96$) but is significantly associated with overall survival ($p = 0.01$)

Supplemental Table 13. Rate of information gain with successive datasets

Sets	Genes per set	Genes already found in prior set	Genes per set	Genes already found in prior set
9C_9	666	0	1736	0
9C_8	1870	656 (35.1%)*	6757	1528 (22.6%)*
9C_7	2286	1466 (64.1%)	8950	3425 (38.3%)
9C_6	2579	2102 (81.5%)	9357	6077 (65%)

* Percentages are number of nodes/edges already found in prior set divided by total numbers of nodes/edges in that dataset

The number of new genes (nodes) and edges (as a percentage of total nodes/genes) decreases as the GC network construction progressed from 9C_9 to 9C_6 . For example, in the 9C_6 data series, of 2579 genes, 2102 were already found in the preceding 9C_7 dataset.

Supplemental Methods

GC Coexpression Network Construction

Affymetrix datasets (JP, SG-2 and LS-1) were normalized using the MAS 5 algorithm¹ and subjected to a *log2* transformation. Custom cDNA microarray datasets (AU-1, HK, SG-1, AMS, KA-1 and SD) were individually normalized and preprocessed by the contributing centers. UniGene Cluster IDs (Build 194) were used to harmonize gene identifiers across the datasets. For datasets lacking UniGene Cluster ID information, the SOURCE website was used to extract UniGene IDs (<http://smd.stanford.edu/cgi-bin/source/>). Distinct array probes mapping to the same UniGene ClusterID were averaged and assigned a single value. In total, 31096 unique UniGene IDs were present across all nine datasets.

The coexpression network was constructed using methods described by Aggarwal *et al*,² with slight modifications. Briefly, first, using rank order statistics, we established a core network using genes common to all nine datasets as network nodes, and visualized gene pairs exhibiting recurrent coexpression associations across the samples as network edges² (Supplemental Figure 10). For each dataset, a ranked correlation matrix containing all pair wise gene-gene correlation coefficients was computed. Using a probabilistic method based on order statistics, we evaluated the probability of observing a particular configuration of ranks across the different GC datasets. Defining the null hypothesis H_0 that the ranked correlations of any gene pair (A, B) across the nine datasets are randomly distributed, and the alternative hypothesis H1 that the (A, B) ranks are non-randomly distributed, a log-likelihood ratio (LLR , $LLR = \log_{10} [p(H_0)/p(H_1)]$) score was computed as an index of gene-gene interaction strength. A false discovery rate (FDR) cut-off was estimated by analyzing 50 randomly permuted datasets where the rank order of genes within each single center dataset was shuffled and the number of ‘significant’ links at each LLR was calculated. This randomization process was

independently repeated 50 times and the results were averaged. Second, we extended the core network by incorporating additional nodes and edges identified by reiteratively applying the same procedure to all possible combinations of eight, seven, and six datasets (i.e. 9C_9 , 9C_8 , 9C_7 , 9C_6). In total, we considered 130 possible combinations with saturation of information gain achieved at six datasets (Supplemental Table 13, Supplemental Figure 11).

Modules (sub-networks of tightly coexpressed genes) within the network were constructed using a previously described ‘chain-linking’ algorithm.² Individual genes were serially connected to additional genes exhibiting the highest interaction strength (‘chain’) until a terminator pair was encountered (i.e. the strongest interacting partner of gene A is gene B and the strongest interacting partner of gene B is gene A). Using this chain as a scaffold, additional genes showing significant interactions with scaffold genes (i.e. $LLR >$ cut-off) were aggregated with the scaffold genes to form a module. In total, 178 modules were identified (Supplemental Document 1).

We elected to use an iterative approach towards the network construction. While analyzing genes common to all nine datasets might provide the most robust associations, adopting such a strict approach would confine our analysis to a relatively small number of genes (666) and limit subsequent biological discovery. For example, a co-expression analysis using the core network of 666 genes revealed only 55 co-expression modules, while a similar analysis using the expanded 3177-gene network revealed 178 modules (2.7x greater) (Supplemental Figure 12). Several biologically relevant modules, such as the digestive super-module and the proteosomal super-module, were absent from the 666-gene core network while being clearly evident in the expanded network based on 3177 genes).

Functional Annotation of Coexpression Modules

Individual modules were mapped against the Molecular Signatures database (MsigDB 2.5, <http://www.broadinstitute.org/gsea/msigdb/>). Four MsigDB sections were queried: C1 (chromosomal position), C2 (pathways, publication and knowledge-based gene sets), C3 (cis-regulatory motifs), and C5 (Gene Ontologies). The hypergeometric distribution was used to compute the overlap significance using $p < 0.001$ and a minimal gene overlap number of at least five genes. All p values were corrected for multiple hypotheses at a $Q\text{-VALUE } FDR < 0.05$, estimated using the Q-VALUE software package (<http://www.genomine.org/qvalue/>). We excluded MSigDB signatures mapping to more than nine modules as these signatures mostly corresponded to general and thus rather non-specific cellular functions (e.g. cytoplasm, membrane) (Supplemental Document 2).

Mapping Module Expression Values to Individual Validation Samples

To study patterns of module expression in individual samples, we derived surrogate expression signatures for each module. For 153 modules, these surrogate signatures contained the module ‘hub’ gene (defined as the gene exhibiting the greatest number of connections in the module), immediate neighboring genes positively correlated to the hub, and other module genes with positive correlations to the immediate neighboring genes. For 25 modules where the hub gene was linked to neighboring genes predominantly by negative correlations, a surrogate expression signature reflecting the predominant trend of expression amongst genes in the module was created by excluding the hub gene, including immediate neighboring genes positively correlated to the hub, and other module genes with positive correlations to the immediate neighboring genes. Supplemental Document 3 provides a list of signature genes from all modules. The GENOMICA program was used to compare levels of module expression between samples.³ To discover molecular patterns based on module expression, we

combined all 349 cancers and normal samples from the three validation datasets (SG-3, AU-2 and YGC) and clustered them based on their module expression patterns using average linkage hierarchical clustering and a centered correlation similarity metric. Cluster and Treeview (<http://rana.lbl.gov/EisenSoftware.htm>) software were used for clustering and generating module expression heat maps. Supplemental Table 5 lists the top 20 hub genes of the current GC coexpression network (*FDR* < 0.001).

Clinicopathological Variables

Mann-Whitney U tests were used to evaluate relationships between levels of module expression and clinicopathological variables. Patients were divided into two groups based on different clinical variables: age (<65 years *vs.* \geq 65 years), gender (male *vs.* female), disease stage (early stage (UICC/AJCC stage I and II) *vs.* late stage (UICC/AJCC stage III and IV)), histopathological subtype (intestinal type *vs.* diffuse type), and grade of differentiation (low *vs.* high). A threshold of \geq 65 years was used to define "old age" based on the observation that in several Western European countries (UK, Germany, Ireland), 65 years is the age at which the state will first offer a pension (<http://www.vicon-project.eu/node/10>). Clinicopathological associations observed in the combined validation series (349 samples, SG-3, AU-2 and YGC) with a *p*-value < 0.05 were considered significant. *p*-values were corrected for multiple hypotheses by Q-VALUE software.

Mapping of Oncogenic Pathways

Mapping of gene expression signatures representing oncogenic pathways was performed as previously described.⁴ Relationships between oncogenic pathway activation and super-module

expression values were evaluated using Pearson's correlation coefficient and a *p*-value < 0.05 was considered significant. *p*-values were corrected for multiple hypotheses by Q-VALUE software.

Survival Analysis

Kaplan-Meier analysis (SPSS, Chicago) was used to perform survival comparisons in patient datasets where clinical follow up and mortality information were available, e.g. SG-3: *n* = 153 GCs, AU-2: *n* = 70 GCs, YGC: *n* = 65 GCs, AMS: *n* = 34 GCs and LS-2: *n* = 131 GCs. Differences in survival probability were computed using two different approaches: Cox regression analysis with Wald test (CR) and Kaplan-Meier analysis with log rank test (KM). For CR, we analyzed stromal module expression as a continuous variable, and for KM we compared the one third of patients with the highest stromal super-module expressing GCs to the one third of patients with the lowest stromal super-module expressing GCs. Data from the third of patients with intermediate levels of stromal module expressing GCs were excluded from KM analysis to allow comparisons between biological extremes. *p*-values of < 0.05 were considered significant. Overall survival was used as an endpoint for the gene expression datasets, and cancer specific survival was used for the TMA dataset (LS-2). Patients who died within 30 days after surgery (post-operative mortality) were excluded from cancer specific survival analyses. Multivariate analysis was performed using Cox proportional hazards modeling including all covariates identified as significantly related to patient survival in univariate analyses. Data from the third of patients in LS-2 with intermediate levels of ITS ([40.76%, 61.8%]) GCs were excluded from KM analysis.

Immunohistochemical Analysis

To validate the expression of stromal genes, we elected to perform VIM and CALDESM immunohistochemistry. We chose VIM and CALDESM as they a) displayed high connectivity in the

stromal super-module (CALDESM : 61 neighboring edges/nodes; VIM : 9 neighboring edges/nodes); b) were independently associated with patient survival at the gene expression level, ; and c) immunohistochemical assays for these markers are already well established in routine diagnostic histopathology laboratories albeit for different purposes. Briefly, 4 micron sections were cut onto Superfrost Plus slides and dried overnight. After deparaffinsation, sections were subjected to antigen-retrieval in a microwavable pressure cooker in 10mM citrate buffer, pH6. Endogenous peroxidase was blocked by incubating the slides in 3% H₂O₂/distilled water and endogenous biotin was blocked using an egg white solution. Sections were incubated with primary antibodies for 1 hour at 37 degree C (anti-vimentin 1:50 dilution (DAKO M7020); anti-caldesmon 1:200 dilution (DAKO M3557). The DAKO REAL streptavidin biotin kit was used as a detection system according to the manufacturer's instructions. DAB was used as a chromogen, sections were counterstained with Mayer's hematoxylin, dehydrated and coverslipped with DPX.

Quantitation of Intra-Tumoral Stroma (ITS) by Computerized Point Counting

The ITS proportion of both, full sections and tissue microarrays (TMAs), was quantitated by point counting as described by West et al. (2010).⁵ For full sections, 4 μm thick sections were cut from paraffin embedded GC tissue blocks chosen to represent the deepest tumor infiltration in the gastric wall (highest pT category). TMAs were constructed by random sampling of three to six 0.6mm diameter cores from one representative tumour containing paraffin block from each GC. Full sections and TMA sections were stained with Haematoxylin&Eosin (H&E) according to standard protocols and scanned at 40x magnification using an automated scanning system (Aperio XT, Aperio Technologies, Vista, CA, USA). Virtual slides from full sections and TMA sections were visualized using ImageScope v 10.1.3.2028 (Aperio Technologies). In full sections, the whole area containing tumor

was encircled using a pen tool avoiding areas of necrosis and mucin, whereas all tumour containing cores of an individual GC were encircled in the TMA sections. A grid with a systematic random sample of 300 measurement points was superimposed onto the selected area using virtual graticule software (RandomSpot, University of Leeds, Leeds, UK, freely accessible via <http://129.11.65.182/RandomSpot/>). Each point was scored using the following categories: tumor, stroma, tumor lumen, necrosis, vessel, inflammation and noninformative (unclassifiable). The percentage of measurement points in each category was calculated for each case.

Softwares

Methodologies (rank order statistics, data permutation, coexpression network construction, ‘chain-linking’ algorithm) were implemented in Matlab software (<http://www.mathworks.com>) and C programming language. Network diagrams were visualized using Cytoscape 2.6.0 software (<http://www.cytoscape.org/>). Power law graphs were generated using NetworkAnalyzer (<http://med.bioinf.mpi-inf.mpg.de/netanalyzer/>), a Java plug-in for Cytoscape.
