

EDITOR'S QUIZ: GI SNAPSHOT

Seeing a cause for blindness in severe pancreatitis

During a holiday on a Mediterranean island, a 63-year old woman suffered a severe attack of pancreatitis secondary to gall-stones. During the hospital stay, no sepsis was noted, but she was treated with prophylactic intravenous antibiotics, intravenous fluid and analgesia intensive care support was not required. After 22 days in hospital, she travelled back to the UK and presented to our department on advice to seek further help regarding ongoing symptoms of nausea and reduced appetite. A CT scan performed on admission demonstrated a developing 13×4.5 cm acute pancreatic collection with fat necrosis, splenic vein occlusion and gastric compression. Treatment with analgesia, venous thrombosis prophylaxis and nasojejunal feeding was commenced pending either a possible regression or maturation of the collection when a drainage procedure would be performed. Repeated blood cultures performed for mild fever (37.5°C) were negative. Twelve days later, a repeat CT scan showed persistence of the collection with a walled-off appearance and a coinciding rise in C reactive protein prompted transgastric endoscopic drainage. The following day urgent ophthalmology review was performed as the patient described that she had been seeing 'floaters' for 2 weeks but now was unable to read. Right eye visual acuity was 6/60 and left eye was 6/12 (figure 1).

Figure 1 Ophthalmology examination revealed bilateral intraocular inflammation, with fluffy white preretinal lesions and multiple 'string-of-pearls' signs.

QUESTION

What is the diagnosis? What risk factors does this woman have for developing this condition?

See page 46 for answer

EDITOR'S QUIZ: GI SNAPSHOT

Seeing a cause for blindness in severe pancreatitis

See page 32 for question

ANSWER

These signs were diagnostic of a fungal endogenous endophthalmitis confirmed on a vitreous fluid culture of *Candida albicans*. This condition has a number of associations, including immunocompromise, prolonged intravenous access or drug abuse, and is a sight threatening disease.¹ We believe this is the first case report of a fungal endophthalmitis secondary to translocation from an infected pancreatic fluid collection (PFC). The patient underwent intravitreal amphotericin injections, urgent bilateral vitrectomies, repeated endoscopic drainage and received 6 weeks oral voriconazole and intravenous anidulafungin² (the latter added following endocarditis concerns) (figure 2).

There is a debateable suggestion that there is a strong correlation between fungal positivity in infected PFCs and use or duration of prophylactic antibiotics.³ Current UK guidelines for acute pancreatitis suggest prophylactic antibiotics should be considered only for patients with more than 30% necrosis, but the evidence to make any recommendation is conflicting.⁴ Initial conservative management avoiding drainage of non-infected PFCs is advised⁵ with guidelines recommending diagnostic aspiration or drainage if there are signs of infection.^{4, 5} Given this further demonstration of the severe complications of pancreatitis, we would echo the current UK guideline recommendations of vigilance with prophylactic antibiotic treatment and a low threshold to perform early diagnostic aspiration.
