Titanium dioxide nanoparticles exacerbate 
DSS-induced colitis: role of the NLRP3 inflammasome

INTRODUCTION

The aetiology of IBD remains only partially understood; however, it is now accepted that both Crohn’s disease (CD) and UC are caused by interplay of genetic and environmental factors that trigger an inappropriate immune response. The incidence of IBD is increasing in many nations and is influenced by environmental factors such as ‘westernisation’, supporting an important role of environmental factors during IBD pathogenesis. Among those environmental triggers are the increased hygiene and ‘Western diet’, which includes ingestion of nanoparticles.

Inorganic nanoparticles and microparticles are used as additives to influence the appearance of a dietary product. The most commonly used additives are submicron-sized (100–1000 nm diameter) particles of titanium dioxide (TiO2, E171) and aluminium silicate (E559). Food and pharma grade...
TiO₂ is found both in its bulk form and as nanoparticle. In fact, at least 36% of the TiO₂ particles present in food consists of nanoparticles with a particle diameter less than 100 nm. The daily intake of TiO₂ was estimated by the European Food Safety Authorities in 2004 to be 1.28 mg/kg bodyweight. Further to this, in a dietary study assessing the TiO₂ consumption of patients with CD and healthy volunteers Lomer et al. estimated that the median individual TiO₂ intake in both groups was 2.5 mg/day. A later study estimated a daily intake of TiO₂ food grade of 0.2–2 mg/kg bodyweight, suggesting that TiO₂ is ingested in substantial amounts on a daily basis. To date, no restrictions for the use of TiO₂ are enforced by food safety authorities and only good manufacturing practice guidelines limit the use of these compounds. An increasing body of literature has revealed that exposure to TiO₂ can cause adverse effects, including the production of reactive oxygen species (ROS), inflammatory responses and tumour formation. In mice, TiO₂ nanoparticles cause genotoxic effects in blood cells, bone marrow and liver, and DNA deletions in the offspring. Cytotoxic effects resulting from TiO₂-induced production of ROS were observed in human lymphoblastoid cells, fibroblasts, bronchial epithelial cells and alveolar macrophages, which led to the classification of TiO₂ as ‘possibly carcinogenic for humans’. Nanoparticles can accumulate in several organs, such as kidney, lung, brain, liver and spleen. In intestinal biopsies, dark aggregates of TiO₂ were detected in M-cells of Peyers patches and in underlying macrophages. Interestingly, these sites of TiO₂ uptake correspond to regions where first signs of inflammation in patients with CD manifest.

Nucleotide-binding oligomerisation domain receptor, pyrin domain containing (NLRP)3 is a member of the Nod-like receptor (NLR) family that regulates the activation of caspase-1 by forming signalling complexes called ‘inflammasomes’. On activation, NLRP3 binds to the apoptosis-associated speck-like protein containing a caspase recruitment domain (ASC) adapter protein, which in turn recruits and activates caspase-1. Activated caspase-1 cleaves pro-interleukin (IL)-1β and pro-IL-18 into their biologically active forms. Single nucleotide polymorphisms in the Nlrp3 gene have been linked to the development of CD. NLRP3 has been shown to be activated by a wide range of pathogens and intrinsic danger signals like ATP, ROS, crystalline monosodium urate, cholesterol crystals and inorganic materials like aluminium salts, asbestos and silica crystals. Similarly, inorganic TiO₂ nanoparticles activate the NLRP3 inflammasome and induce a proinflammatory response in human keratinocytes, human dendritic cells and murine macrophages.

In the present study, we analysed the effect of TiO₂ on intestinal inflammation as well as the contribution of the NLRP3 inflammasome in TiO₂-mediated inflammatory responses. For this purpose, we used the dextran sodium sulfate (DSS) acute colitis model in the wild-type (WT) and NLRP3-deficient (Nlrp3−/−) mice. Oral administration of TiO₂ nanoparticles worsened intestinal inflammation through NLRP3. Moreover, crystals were found to accumulate in splenic tissue of TiO₂-administered mice, but not in those receiving water. In vitro experiments showed that both TiO₂ nanoparticles and food grade TiO₂ microparticles trigger proinflammatory cytokine secretion through NLRP3 inflammasome activation, and accumulate in human intestinal epithelial cells (IECs) and macrophages. TiO₂ particles induced ROS production in IECs and increased epithelial permeability. Finally, an increase of titanium burden in blood of patients with UC having active disease was found, evidencing an impaired barrier function and suggesting that TiO₂ nanoparticles could pose a specific risk to patients with IBD.

**MATERIAL AND METHODS**

**Mouse experiments**

Acute colitis was induced in female WT (C57BL/6) and Nlrp3+/− mice between 12 and 14 weeks of age by oral administration of 1.5% DSS (MP Biomedicals) in drinking water ad libitum for 7 days. A suspension of TiO₂ nanoparticles (rutile, 30–50 nm, LoLiTeC) in drinking water was administered daily by oral gavage. WT mice were divided in three groups of 12 mice each, and received water, 50 or 500 mg TiO₂/day/kg bodyweight. Nlrp3−/− mice received water (n=10) or 500 mg TiO₂/day/kg bodyweight (n=10). On day 8, colitis was assessed by endoscopy and mice were sacrificed for sample collection. All the animal experiments were approved by the veterinary authorities of Zurich, Switzerland.

**Colonoscopy and determination of histological score**

Animals were anaesthetised intraperitoneally with a mixture of ketamine 90–120 mg/kg bodyweight (Vetquotinol) and xylazine 8 mg/kg bodyweight (Bayer), and colonoscopy was performed as described previously. Animals were sacrificed and colon length was measured. About 1 cm of tissue was removed from the distal third of the colon and fixed in 4% formalin overnight. H&E stained sections of the paraffin-embedded tissue were used for histological analysis. Histological score was determined as described previously by two independent, blinded investigators.

**Western blotting and co-immunoprecipitation**

Total protein from cell monolayers was harvested into M-PER lysis buffer (Thermo Fisher Scientific) and western blotting was performed to determine the expression of NLRP3 (Enzo life sciences), caspase-1, ASC, IL-1β (Cell Signaling Technologies) and IL-18 (MBL). Co-immunoprecipitation (Co-IP) was performed overnight at 4°C using NLRP3 antibody. Immunocomplexes were collected with Protein G Sepharose beads (GE Healthcare) for 1 h at 4°C prior to western blotting.

**Microscopy of spleen cryosections and Caco-2 monolayers**

Confocal reflection microscopy was combined with fluorescence microscopy in a Leica SP8 laser scanning confocal microscope, as described previously. Caco-2 cells grown on coverslips and transwells were fixed with 4% PFA for 20 min. Coverslips were directly subjected to H&E staining. Cryosections of transwells with Caco-2 monolayers were cut at cryogenic temperatures at 5–20 μm thickness. Sections were stained with H&E or DAPI-containing mounting medium (Vector Laboratories) and images were captured using a fluorescent microscope (Axioplan2, Zeiss). For electron microscopy, Caco-2 cells were fixed and embedded in Epon according to established protocols. Electron microscopic analysis, including elemental analysis was performed with a CM12 electron microscope (FEI) equipped with an EDX detector (Genesis, EDAX). For quantification of intracellular microparticles, 5 μm sections of TiO₂-stimulated Caco-2 monolayers grown on transwell membranes were used. Particles and aggregates of TiO₂ were counted in phase-contrast view, and DAPI-stained nuclei were counted in blue fluorescent channel.

**Cell culture and reagents**

THP-1 cells were maintained in RPMI medium (Invitrogen) supplemented with 10% fetal calf serum (VWR). To induce differentiation, 40 nM phorbol-12-myristate-13-acetate (Sigma-
Isolation and stimulation of bone marrow-derived macrophages

Mononuclear phagocyte progenitor cells were flushed from femoral and tibial bones from C57/BL6 mice with cell culture medium. After centrifugation, cells were resuspended in medium containing 30 mg/mL recombinant murine macrophage-stimulating factor (Biovision) and kept for 5 days before stimulation with 20 μg/mL TiO₂ and 5 μM cytochalasin D (Invivogen).

ELISA analysis

ELISAs directed against active forms of IL-1β (R&D Systems) and IL-18 (MBL) were conducted with cell culture supernatants according to manufacturer’s instructions.

Small interfering RNA knockdown of inflammasome components

Undifferentiated THP-1 cells were transfected with three sets of small interfering RNAs (siRNAs) for caspase-1, ASC and NLRP3 at a concentration of 100 pmol each, and electroporated using the Amaxa nucleofector kit (Mirus Bio LLC) following manufacturer’s instructions.

Assessment of lysosomal integrity

Caco-2 and HT-29 cells were stained with 1 μg/mL acridine orange (Sigma-Aldrich) for 15 min prior to TiO₂ and cytochalasin D stimulation. Lysosomal rupture was analysed by fluorescent microscopy (Axioplan2, Zeiss).

Measurement of ROS production

IECs were incubated with Hank’s balanced salt solution (HBSS) (Sigma-Aldrich) containing 50 μM of dihydro-dichlorofluorescein diacetate (Sigma-Aldrich) for 30 min at 37°C. ROS-induced fluorescence was detected using a microplate reader with an excitation wavelength of 485 nm and an emission wavelength of 528 nm.

Epithelial permeability studies

Caco-2 cells were grown as monolayers on transwell membranes as described above. Flux of fluorescein isothiocyanate-dextran beads (average molecular weight 40 000, Sigma-Aldrich) was measured 2 h after addition of 1 mg/mL beads to the apical compartment. Fluorescence intensity in aliquots from the basolateral compartment was measured using a microplate reader with an excitation wavelength of 485 nm and an emission wavelength of 525 nm.

Human subjects

The study was conducted as a subproject of the Swiss IBD Cohort Study and was approved by the Ethics Committees (EK 1316). Prior to inclusion into the study, written informed consent was obtained from all patients. Inclusion criteria for enrolment of patients with IBD having active disease were 18–80 years of age and at least one episode of active disease between 1 September 2010 and 31 August 2011. Flare-up episodes reported by the patient were verified by a physician in the course of a clinical examination. Inclusion criteria for enrolment of patients with IBD in clinical remission were 18–80 years of age and maintenance of clinical remission between 1 September 2010 and 31 August 2011. Exclusion criteria in this study were perianal CD and positive results of microbiological workup of faecal samples for known infectious agents. Clinical activity in patients with CD and patients with UC was assessed using the Harvey Bradshaw Index (HBI) and the Rachmilewitz Index, respectively. A flare-up episode in patients with CD was defined as a rise in HBI value of ≥4 points. A flare-up in patients with UC was defined as an increase in the Rachmilewitz Index value of ≥5 points. Titanium levels in blood samples from healthy volunteers (n=28), patients with UC having active disease (n=5), patients with UC in remission (n=6), patients with CD having active disease (n=8) and patients with CD in remission (n=9) were measured by inductively coupled plasma mass spectrometry (ICP-MS) at the Department of Forensic Pharmacology and Toxicology of the University of Zurich, Switzerland.

Inductively coupled plasma mass spectrometry

Sample preparation for ICP-MS

All calibration standard solutions were prepared from 1 mg/mL single element standard solutions (Merck) by dilution with ultrapure water. About 0.5 mL of whole blood from patients was diluted in 4.5 mL ultrapure water and infused into the ICP-MS. Seronorm trace elements whole blood samples (level 3; titanium concentration: 24 μg/L; accepted range 20–28 μg/L) were prepared in the same manner as the whole blood samples from patients and used as control (SERO AS).

ICP-MS

A Varian ICP-MS 810 (low resolution) equipped with type 142 Varian cooler and a Varian SPS 3 Autosampler (Varian) were used with the following measurement parameters: analysis type: quantitative; acquisition mode: steady state; scan mode: peak hopping; spacing: coarse; points/peak: 1; scans/replicate: 50; replicates/sample: 3; plasma flow: 18.00 L/min; auxiliary flow: 1.75 L/min; sheath gas flow: 0.24 L/min; nebuliser flow: 1.00 L/min; sampling depth: 5.00 mm; power: 1.35 kW; pump rate: 7 rpm; stabilisation delay 0 s; ion optics (volt) version number: 0; first extraction lens: −1.00; second extraction lens: −129.00; third extraction lens: −214.00; left mirror lens: 32.00; right mirror lens: 17.00; bottom mirror lens: 28.00; corner lens: −199.00; entrance lens: −1.00; fringe bias: −4.50; entrance plate: −32.00; detector focus: true pole bias: 0.00; sampling aerosol generation: nebuliser, source: autosampler; fast pump during sample delay/rinse: On; probe height: 0 mm; premix: Off; rinse time: 10 s; spray chamber cooling: on; spray chamber temperature: 3.0°C; sample uptake delay: 50 s; smart rinse: No; switch delay: OFF; scan time: 1415 ms; replicate time: 70.75 s; titanium isotope for quantification: 49. All chemicals (eg, water, acid, hydrogen peroxide) and materials (eg, tubes, blood Monovettes including needles) were checked for interferences. All results were under the detection limit of the procedure (0.25 μg/L). Calibration was done in every series, using standard solutions of 1, 10 and 100 μg/L Titanium and a blank. The results of the Seronorm quality control samples were very good. Mean (n=14) of the results of the Seronorm control
level 3 (target value 24 μg/L) was 24.5 μg/L with a coefficient of variation of 9.6%. Thus, the method was more than suitable for our purposes, especially considering that, while accuracy may be marginally compromised, relative differences between the groups should stay the same.

**Statistics**
Statistical analysis was performed using Student’s t test, Mann–Whitney test or one-way analysis of variance with Dunnett’s post-test. The results are expressed as mean±SEM and significance was set as p<0.05.

**RESULTS**

**Administration of TiO<sub>2</sub> nanoparticles aggravates DSS-induced colitis**

To study the impact of TiO<sub>2</sub> nanoparticles in colitis, and the role of NLRP3 inflammasome in TiO<sub>2</sub>-mediated effects, DSS-treated WT and Nlrp3<sup>−/−</sup> mice were administered with 0, 50 or 500 mg/kg/day TiO<sub>2</sub> nanoparticles by oral gavage. WT mice receiving TiO<sub>2</sub> presented a more severe colitis than mice receiving TiO<sub>2</sub>-free drinking water, as evidenced by a significant shortening of the colon (figure 1A), and colonoscopy results (figure 1B). In contrast, Nlrp3<sup>−/−</sup> mice administered with 500 mg/kg/day TiO<sub>2</sub> showed no differences in colon length or colonoscopy findings compared with WT and Nlrp3<sup>−/−</sup> mice receiving water (figure 1A,B). Similarly, H&E stained sections of colonic tissue presented a significantly higher inflammatory cell infiltration (figure 1C) and total histological score with a severe disruption of the mucosal epithelium in TiO<sub>2</sub>-treated WT, but not Nlrp3<sup>−/−</sup> mice (figure 1D,E). Mice receiving TiO<sub>2</sub> in the absence of colitis did not present shortening of the colon, or increased histological scores (data not shown), suggesting that TiO<sub>2</sub> might be deleterious only in pre-existing inflammation. Recent studies have shown that, after intravenous injection of TiO<sub>2</sub> in rats, significant levels of TiO<sub>2</sub> in spleen and liver were still found 30 days post injection. When applied intraperitoneally in mice, TiO<sub>2</sub> was distributed throughout the entire body but was mainly retained in liver and spleen. In our experimental setting, analysis of splenic cryosections using a combination of confocal and reflexion microscopy revealed that oral administration of TiO<sub>2</sub> led to the accumulation of crystals in the spleen of DSS-treated mice in a dose-dependent manner (figure 1F).

**TiO<sub>2</sub> induces NLRP3 activation and caspase-1 downstream effectors in human IECs and macrophages**

Since IECs have rarely been used in NLRP3 inflammasome studies, protein expression of NLRP3 was confirmed by western blot in human IEC lines (see online supplementary figure S1A). Interestingly, both nanoparticles and microparticles induced IL-1β secretion in the monocytic cell line THP-1 (figure 2A), as well as caspase-1 cleavage (figure 2B) and IL-1β cleavage (figure 2C) in both Caco-2 and THP-1 cells. Co-IP of NLRP3 further evidenced the association of the inflammasome components caspase-1, ASC and NLRP3 on stimulation with both TiO<sub>2</sub>

![Figure 1](https://example.com/figure1.png)
crystal forms (figure 2D). TiO$_2$ microparticles induced IL-18 cytokine secretion in Caco-2 and THP-1 cells (figure 2E,F). Moreover, siRNA knockdown of the inflammasome components NLRP3, ASC and caspase-1 in THP-1 cells significantly reduced the levels of IL-1β in the presence of TiO$_2$ demonstrating that TiO$_2$-induced IL-1β release is NLRP3 inflammasome-dependent (figure 2G).

TiO$_2$ accumulates in human IECs and macrophages in a dose-dependent manner

In agreement with previous reports, incubation of THP-1 cells with food grade TiO$_2$ microparticles led to intracellular accumulation of dark aggregates (figure 3A). Additionally, we observed that TiO$_2$ was taken up by murine BMDMs (figure 3B). Pretreatment of BMDMs with cytochalasin D, an inhibitor of endocytosis, did not inhibit the accumulation of TiO$_2$ aggregates (figure 3C), pointing to an endocytosis-independent uptake mechanism. As the intestinal epithelium is subjected to the major exposure to TiO$_2$, we investigated whether TiO$_2$ also penetrates IECs. Treatment of monolayers of the IEC lines HT-29 and Caco-2 with TiO$_2$ microparticles for 24 h resulted in intracellular accumulation of TiO$_2$ (figure 3D,E). To mimic the physiological setting in the intestine, tight monolayers of Caco-2 cells growing on transwell filters were stimulated apically with TiO$_2$. Cross-sections of these monolayers revealed dark, intracellular aggregates of microparticles (figure 4A,B), which were present in a dose-dependent manner (figure 4C,D). These findings were confirmed by electron microscopy: TiO$_2$ was detectable in cross-sections of Caco-2 monolayers as electron dense aggregates (figure 4E) and elemental analysis of selected areas confirmed that aggregates contained titanium (figure 4F).

TiO$_2$ triggers ROS production and epithelial permeability in IECs

The uptake of TiO$_2$ particles has been associated with the production of ROS, which are major inducers of NLRP3 inflammasome activation via stress-associated signals. Our results show that TiO$_2$ microparticles induced ROS production in HT-29 (figure 5A) and Caco-2 cells (figure 5B) in a dose-dependent manner. Particulate matter has been shown to induce inflammasome activation through lysosomal rupture following endocytosis. To investigate whether this is also the case with TiO$_2$ microparticles, lysosomal staining with acridine orange was performed on IECs stimulated with TiO$_2$. Fluorescence microscopy did not show any loss of lysosomal integrity in TiO$_2$-treated Caco-2 and HT-29 cells (see online supplementary figure S2A–C). Based on our results showing intracellular accumulation of TiO$_2$ in epithelial monolayers, we sought to...
investigate the effects of TiO₂ on epithelial permeability. For this purpose, we used the transwell model system with Caco-2 cells, which form tight monolayers with an apical-basolateral polarity. The treatment of Caco-2 with 20 μg/mL TiO₂ resulted in a significant increase of epithelial permeability (figure 5C).

Patients with UC having active disease present increased levels of titanium in systemic circulation

Given the increased permeability in the mucosa of patients with IBD, and based on our findings showing the proinflammatory effects of food-derived TiO₂ and its ability to traverse the intestinal mucosa in vivo, we hypothesised that patients with IBD may have a higher systemic burden of titanium. Using ICP-MS, we assessed the levels of titanium in whole blood of healthy donors and patients with IBD. Initial data analysis did not reveal significant differences in titanium levels when comparing healthy donors with patients with IBD (figure 6A). However, we observed significantly higher titanium levels in the subgroup of patients with UC having active disease (figure 6B).

**DISCUSSION**

Our results show that oral administration of TiO₂ nanoparticles enhances intestinal inflammation in the DSS mouse model of colitis. Although TiO₂ concentrations used are higher than the amounts the human gut is daily exposed to, the results obtained suggest that TiO₂ is biologically active and support a growing body of literature evidencing the deleterious effects of TiO₂ *in vivo*. TiO₂ proinflammatory effects required NLRP3 inflammasome activation as shown when comparing WT with *Nlrp3<sup>−/−</sup>* mice. The role of NLRP3 in DSS colitis is controversial with reports showing detrimental and protective roles for NLRP3. In our study, 1.5% DSS induced a mild inflammation in WT and *Nlrp3<sup>−/−</sup>* mice and we did not detect significant differences between the two groups. Despite the relatively large consumption of TiO₂, stability and aggregation in GI fluids has received limited attention. Recent studies using in vitro human digestion models have shown that SiO₂ and Ag nanoparticles, which agglomerated under conditions of low pH and high electrolytes as in the gastric compartment, become bioavailable under intestinal conditions. Our mouse experiments demonstrate a dose-dependent accumulation of crystals in the spleen, pointing to the fact that ingested TiO₂ can traverse the intestinal mucosa and reach the systemic circulation. This finding agrees with recent studies showing that TiO₂ nanoparticles translocate through the intestinal epithelium and accumulate in the spleen in orally administered mice. Of note, we could not find accumulation of TiO₂ crystals in the colonic epithelium, suggesting that TiO₂ nanoparticles are mostly absorbed in the small intestine. This is in accordance with previous studies showing that TiO₂ particles translocate through the epithelium lining the small intestine, in particular Peyers patches. We show that TiO₂ nanoparticles and microparticles induce NLRP3-ASC-caspase-1 assembly and caspase-1 cleavage, resulting in the release of functionally active IL-1β in Caco-2 and THP-1 cells in the absence of other stimulus. TiO₂ microparticles also induced IL-18 secretion in both cell lines. Since TiO₂ microparticles contain a significant amount of nanosized particles, it is likely that the effects observed on microparticle stimulation are due, at least in part, to the presence of TiO₂ nanoparticles. Knockdown of NLRP3, ASC and caspase-1 abrogated TiO₂-induced IL-1β expression in macrophages, evidencing the crucial role of the NLRP3 inflammasome in TiO₂-mediated proinflammatory responses. In vitro experiments showed that TiO₂ microparticles are taken up by human non-phagocytic IECs as well as macrophage-like THP-1 cells. In agreement with previous reports showing that TiO₂ particles can enter cells via non-endocytic mechanisms, our results point to that TiO₂ uptake was not endocytosis-mediated, and no specific subcellular structure was found to be associated with TiO₂ accumulations. Moreover, we did not observe an involvement of lysosomal structures or TiO₂-induced lysosomal damage, suggesting that TiO₂ particles might interact with lipid membranes and are passively transported into cells, as seen with silica nanoparticles. TiO₂ particles were shown to disturb...
epithelial barrier function in Caco-2 monolayers. Although small, this effect hints to an influence of TiO₂ in epithelial permeability, and is in accordance with studies showing that TiO₂ nanoparticles induce tight junction remodelling in the intestinal epithelium of mice.51 Mimicking human gut exposure to TiO₂ particles in vitro meets often with difficulties: as TiO₂ particles are in an aqueous suspension, they tend to precipitate forming blankets by the end of the incubation time. This might negatively affect cellular responses on TiO₂ stimulation, especially at high concentrations. The detection of significant ROS production in TiO₂-stimulated IECs is in line with previous studies showing that uptake of particulate matter is accompanied by ROS production and inflammasome activation.29 55 Strikingly, ICP-MS analysis revealed increased levels of titanium in the blood of patients with UC having active disease, pointing to that the disturbed barrier function associated with IBD allows for a higher translocation of TiO₂ nanoparticles into the systemic blood stream. Absorbed TiO₂ might enhance inflammation and barrier permeability, facilitating further TiO₂ penetration on subsequent exposures. This would support the suggested therapeutic benefit from low inorganic particle diet observed in patients with IBD. For example, the reduction of nano and microparticles in the diet of patients with CD significantly decreased their disease activity within a month of treatment.56 In contrast, a posterior multi-centered follow-up with 83 patients with CD did not show any effect of a microparticle free diet.57 However, in this trial dietary calcium was also restricted, and effects may have been masked by the corticosteroid treatment received by the participants of the study.

In summary, these findings show that orally administered TiO₂ nanoparticles worsen intestinal inflammation in mice through the activation of NLRP3 inflammasome. TiO₂ is one of

Figure 4  Aggregates of titanium dioxide (TiO₂) accumulate intracellularly in Caco-2 cells in a dose-dependent manner. (A and B), Caco-2 cells grown on transwells were incubated with 100 μg/mL TiO₂ for 24 h. Cross-sections were stained with H&E (A) or DAPI to visualise nuclei and the same frame was observed in phase-contrast view to identify TiO₂ aggregates (B). Scale bar: 25 μm. TiO₂ aggregates were located intracellularly in aggregates of various sizes, indicated by arrows. (C–F) Cross-sections were processed as described above, and TiO₂ aggregates and nuclei were counted. Incubation of Caco-2 for 24 h with indicated amounts of TiO₂ resulted in a dose-dependent increase of intracellular TiO₂ (C). The size of TiO₂ aggregates also increased in a dose-dependent manner. Electron dense regions with a diameter larger than 3.5 μm were considered as large aggregates (D). Cross-sections were subjected to transmission electron microscopy, revealing electron-dense aggregates indicated by arrows (E). The elemental analysis of a selected region (indicated as asterisk in panel E) confirmed that aggregates contained titanium, which appeared as main peak at 4.5 keV (indicated by arrow) (F).

Figure 5  Titanium dioxide (TiO₂) triggers production of reactive oxygen species (ROS) and influences epithelial permeability in human intestinal epithelial cells (IECs). (A and B) HT-29 showed significantly increased production of ROS at the highest dose of 100 μg/mL of TiO₂ (A). In Caco-2 cells, a significant increase of ROS was detected at TiO₂ concentrations of 20 and 100 μg/mL (B). (C) Monolayers of Caco-2 cells were treated with indicated amounts of TiO₂ for 24 h, and incubated apically with FITC-labelled beads for 1 h. An increase of basolateral fluorescence was observed in TiO₂-treated cells as compared with non-treated cells (n=5, **p<0.05).
the most produced nanomaterials in the world and its use as food additive is on the rise. Since TiO$_2$ is also used in pharmaceutical formulations, local luminal concentrations of TiO$_2$ might reach substantial levels. Depending on the properties of the pills, they disintegrate at different sections of the GI tract and can affect the epithelium in a very distinct and concentrated manner. A local accumulation of TiO$_2$ may have profound effects on patients with a disturbed barrier function as found in IBD. Very high concentrations of particles are often chosen in toxicity studies to ensure bioactivity across the assays evaluated. Hence, there is a pressing need for biologically relevant human exposure information to facilitate interpretation of assay results. Since the long-term effects of dietary TiO$_2$ may be revealed only in decades, after a lifetime exposition to TiO$_2$, our data suggest a more cautious use of these particles.
