ABSTRACT

Objective Pancreatic cancer is associated with an abundant stromal reaction leading to immune escape and tumour growth. This massive stroma drives the immune escape in the tumour. We aimed to study the impact of β ig-h3 stromal protein in the modulation of the antitumoural immune response in pancreatic cancer.

Design We performed studies with *p48-Cre;Kras^{G12D}*, *pdx1-Cre;Kras^{G12D};Ink4a/Arf^{fl/fl}*, *pdx1-Cre;Kras^{G12D}*, *p53^{R172H}* mice and tumour tissues from patients with pancreatic ductal adenocarcinoma (PDA). Some transgenic mice were given injections of anti- β ig-h3, anti-CD8, anti-PD1 depleting antibodies. Tumour growth as well as modifications in the activation of local immune cells were analysed by flow cytometry, immunohistochemistry and immunofluorescence. Tissue stiffness was measured by atomic force microscopy.

Results We identified β ig-h3 stromal-derived protein as a key actor of the immune paracrine interaction mechanism that drives pancreatic cancer. We found that β ig-h3 is highly produced by cancer-associated fibroblasts in the stroma of human and mouse. This protein acts directly on tumour-specific CD8⁺ T cells and F4/80 macrophages. Depleting β ig-h3 *in vivo* reduced tumour growth by enhancing the number of activated CD8⁺ T cell within the tumour and subsequent apoptotic tumour cells. Furthermore, we found that targeting β ig-h3 in established lesions released the tissue tension and functionally reprogrammed F4/80 macrophages in the tumour microenvironment.

Conclusions Our data indicate that targeting stromal extracellular matrix protein β ig-h3 improves the antitumoural response and consequently reduces tumour weight. Our findings present β ig-h3 as a novel immunological target in pancreatic cancer.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDA) is a highly aggressive cancer with a median survival of less than 6 months and a 5-year survival rate of 3%–5%.¹ PDA evolves through a series of pancreatic intraepithelial neoplasias (PanINs) that are accompanied by genetic modifications. Of these, the earliest and most ubiquitous is the oncogenic activation of Kras.² In addition to the molecular and histological alterations that define cancer cells, a hallmark of PDA

Significance of this study

What is already known on this subject?

- Pancreatic cancer is a highly aggressive cancer associated with an extensive stromal reaction that blocks access of both the immune system and chemotherapies.
- Pancreatic cancer patients with high densities of CD8⁺ T cells in the juxtatumoural compartment have longer survival times.
- Cancer-associated fibroblasts within the stroma are able to attract and sequester CD8⁺ T cells in the extratumoural compartment.

What are the new findings?

- Stromal β ig-h3 protein is highly expressed by cancer-associated fibroblasts in pancreatic cancer.
- Stromal β ig-h3 protein acts directly on tumour-specific CD8⁺ T cells by reducing their proliferation and activation.
- Depletion of β ig-h3 results in significantly decreased tumour growth, which was associated with increased local antitumour immunity.

How might it impact on clinical practice in the foreseeable future?

- Targeting β ig-h3 within pancreatic tumour represents a promising therapeutic approach.
- Expression of β ig-h3 during tumourigenesis might be used as a potential marker of early detection of pancreatic ductal adenocarcinoma.

is the prominent stromal reaction that surrounds the neoplastic cells. The cellular component of the stroma includes immune cells, such as lymphocytes, macrophages and myeloid-derived suppressor cells (MDSCs), along with vascular and neural elements (i.e. endothelial cells and neurons, respectively) as well as cancer-associated fibroblasts (CAFs).

It is now well established that activated pancreatic stellate cells (PSCs) are the major population of cells that is responsible for the production of this collagenous stroma.³ PSCs represent, at steady state, approximately 4% of the pancreas. They become activated on inflammation and are then converted

into CAFs. Recent studies have demonstrated that CAFs are able to attract and sequester CD8⁺ T cells in the extratumoural compartment. This effect dampens their contact with and consequent clearing of tumour cells.⁴ Several studies performed in mice have shown that depleting CAFs abolishes immune suppression,^{5,6} indicating that they play an important role in modulating the local antitumoural response. In most solid tumours, as in PDA, CD8⁺ T cell infiltration into the tumour is a factor associated with a good prognosis.^{7,8} PDA patients with high densities of CD8⁺ T cells in the juxtatumoural compartment have longer survival times than patients with lower densities.^{4,9} Therefore, restoring the antitumoural CD8⁺ T cell response might be very important in PDA.

βig-h3 (also known as TGFβi) is a 68 kDa extracellular matrix (ECM) protein that was first isolated from A549 human lung adenocarcinoma cells that were treated with transforming growth factor beta (TGF-β).¹⁰ The physiological functions of βig-h3 have been proposed to include cell–matrix interactions and cell migration.¹¹ βig-h3 has also been shown to bind to several ECM molecules, such as collagens I, II and IV and fibronectin, proteoglycans and périostine.^{12,13} At the cell surface, βig-h3 has been shown to interact with various integrins, including α_vβ₃,¹⁴ α₁β₁¹⁵ and α_vβ₅.¹⁶ We recently showed that βig-h3 repressed diabetogenic T cell activation by interfering with early factors in the TCR signalling pathway, such as Lck.¹⁷ We found that βig-h3 expression was increased in some cancers, including pancreatic cancer,¹⁸ whereas in other cancers, such as ovarian cancer and multiple myeloma, the levels of βig-h3 were reduced.^{19,20} Because the expression of βig-h3 was higher in pancreatic cancer, which is associated with an increase in immune suppression, we hypothesised that βig-h3 might play a role in directly modulating the antitumoural immune response.

To study the mechanism of βig-h3 modulation of the antitumoural immune response in pancreatic cancer, we took advantage of engineered mouse models of spontaneous pancreatic neoplasia and cancer that were based on Kras^{G12D} activation in pancreatic cells.^{21,22} Using these models, we evaluated the effect of depleting βig-h3 on the modulation of antitumour immunity and its subsequent impact on tumour growth.

RESULTS

βig-h3 is highly expressed in pancreatic neoplasias and cancers

We previously showed that βig-h3 is expressed at low levels in the islets of Langerhans within the mouse pancreas and is not detected in acinar or duct cells within the normal mouse exocrine compartment.¹⁷ Because the expression level of βig-h3 was increased in PDA,¹⁸ we sought to investigate the kinetics of its protein expression during tumourigenesis. We took advantage of the *p48-Cre;Kras^{G12D}* (KC) mouse model, developing PanINs in mice from 1.5 months old.²² We found that βig-h3 was expressed around neoplastic PanIN lesions starting at 1.5 months after birth in KC animals but was not expressed in the exocrine compartments of control mice (figure 1A). An analysis of the later stages of neoplastic development (ie, at 4.5 and 7 months old) revealed that βig-h3 expression was maintained around PanINs lesions at these ages (figure 1A). To evaluate the expression of βig-h3 in mouse PDA, we next used *pdx1-Cre;Kras^{G12D};Ink4a/Arf^{fl/fl}* (KIC) and *pdx1-Cre;Kras^{G12D};p53^{R172H}* (KPC) mice, which develop adenocarcinoma at 5 weeks old and 16 weeks old, respectively.²³ We found that βig-h3 was strongly expressed in the invasive carcinoma of both the KIC and KPC animals (figure 1B). To confirm the relevance of our observations

in patients with pancreatic cancer, we next analysed a cohort of 12 human PDA biopsies. Interestingly, we found that all analysed tumours strongly expressed βig-h3 in the extracellular compartment of the developed carcinoma (figure 1C and online supplementary figure S1). Altogether, these data suggest that βig-h3 expression is induced in the pancreas beginning in the earliest stage of PanIN onset. Our results further indicate that βig-h3 expression is maintained during the course of tumour progression in both mouse models of PDA and human pancreatic cancers.

βig-h3 is produced in the stromal compartment of pancreatic neoplastic and tumour lesions

Because βig-h3 was detected in pancreatic neoplastic and tumour lesions, we next investigated whether βig-h3 is produced by the tumour cells themselves or by the stroma-tumour microenvironment (TME). To resolve this issue, we performed coimmunofluorescence experiments using cytokeratin19 (CK19), a marker of ductal tumour cells, and PDGFRα, which was previously shown to be a specific surface marker for CAFs.²⁴ As shown in figure 2A, we found that βig-h3 expression was mainly localised in PDGFRα⁺ stromal cells. PDGFRα also co-localised with αSMA, another hallmark of myofibroblasts (figure 2A).²⁵ These observations were further confirmed in the PDA from KIC mice (figure 2B, online supplementary figure S2A,B). Interestingly, we found that βig-h3 expression was mutually exclusive with the expression of CK19 in all analysed PanINs, suggesting that duct cells lack βig-h3 expression (figure 2A,B and online supplementary figure S2B).

Next, we used CD45, EPCAM and PDGFRα, which are cell surface markers, to sort neoplastic duct cells (CD45⁺EPCAM⁺) and CAFs (CD45⁺PDGFRα⁺) in samples obtained from 2.5-month-old KC mice pancreatic tissues (figure 2C and online supplementary figure S2). We used EPCAM as a marker to sort live ductal cells since they coexpressed CK19 and EPCAM (online supplementary figure S2A). Quantitative reverse transcription (RT)-PCR analysis was performed on the sorted cells, and the results confirmed that βig-h3 was more strongly expressed in CAFs than in neoplastic ductal cells (figure 2D). To further validate this result, CAFs and ductal cells were cultured in vitro for 48 hours in the presence or absence of TGF-β1 prior to quantification using a βig-h3 ELISA kit. An analysis of the cell culture supernatants confirmed that while CAFs produce βig-h3 *ex vivo* (219±12.3 pg/mL), it was barely detected in the supernatants of isolated ductal cells (28±13.5 pg/mL) (figure 2E). Interestingly, we found that stimulation with TGF-β1 potentiated the production of βig-h3 by both ductal cells and CAFs, yet the quantity of βig-h3 produced by TGF-β1-stimulated ductal cells never exceeded the basal level of βig-h3 that was produced by CAFs (figure 2E). Taken together, these data show that βig-h3 is produced mainly by PDGFRα⁺ CAFs within the stromal compartment of KC mice.

Secreted βig-h3 decreases Ag-specific CD8⁺ T cell proliferation

Recent studies showed that CAFs attract and sequester CD8⁺ T cells in the extratumoural compartment to decrease their contact with and the consequent clearance of tumour cells.⁴ We previously showed that βig-h3 inhibits the capacity of diabetogenic CD8⁺ T cells to kill islet β-cells.¹⁷ Because we found that βig-h3 is expressed in PanINs and the PDA stromal compartment, we hypothesised that it may also impact T cell functions within the TME. Based on these observations, we sought to determine

Figure 1 β ig-h3 is expressed during early tumorigenesis in pancreatic cancer. Representative immunohistochemical staining for β ig-h3 in the pancreas in KC (A) Wild type (WT) mice at 1.5 months, 4.5 months and 7 months old; (B) WT KIC mice at 2 months old and KPC mice at 3 and 5 months old. (C) Representative PDA patients (1–4) are shown. Scale bar, 100 μ m (upper) and 25 μ m (lower). whether β ig-h3 modulates Ag-specific responses in CD8⁺ T cells. We evaluated the capacity of β ig-h3 to suppress the proliferation of ovalbumin-specific CD8⁺ T cells in OT1 transgenic mice that were treated with the cognate peptide Ag. We treated 5,6-carboxyfluorescein diacetate succinimidyl ester (CFSE)-labelled OT1 splenocytes with recombinant β ig-h3 (r β ig-h3) and then activated these cells with a specific ovalbumin SIINFEKL cognate peptide. We found that treatment with β ig-h3 significantly decreased Ag-specific proliferation, which was measured as the number of divided OT1 cells that expressed the activation markers CD69 and CD44 (online supplementary figure S3A,B). Next, having shown that CAFs produce β ig-h3 (figure 2E), we assessed the impact of the production of β ig-h3 by CAFs on T cell activation. Using conditioned media, we found that CAF culture supernatants were capable of blocking proliferation in OT1 cells and that this effect was reversed by the addition of an anti- β ig-h3-depleting-Ab (online supplementary figure S3C).

To re-stimulate T cells obtained from KC mice, we generated a KC cell line (94% C57BL/6J background, online supplementary table 1) from pancreatic tissues obtained from 2.5-month-old mice, as previously described.²⁶ As expected, the cell line containing ductal and stromal components (online supplementary figure S4A) produced high levels of β ig-h3 (as shown in ELISA), and this effect was strongly decreased by the addition of an anti- β ig-h3-depleting Ab (online supplementary figure S4B). Next, we cocultured CFSE-stained T cells that were obtained from the pancreatic draining lymph nodes of KC mice with mitomycin-treated pancreatic KC cell line. The activation and proliferation of CD8⁺ T cells was subsequently evaluated in these cocultures using FACS analysis after the cells were stimulated for 5 days with an anti- β ig-h3-depleting antibody (Ab) or an isotype control. Using this approach, we found that CD8⁺ T cells that were cocultured with KC cells proliferated and expressed CD44, a marker of activation (figure 3A). More importantly, the addition of anti- β ig-h3-depleting Abs to the cell coculture resulted in a higher rate of proliferation in CD8⁺CD44^{high} T cells than that was observed in control Ab-treated cells (figure 3A). Furthermore, we found that CD8⁺ T cells that were stimulated by the KC cell line subsequently expressed increased levels of cell exhaustion markers such as programmed death receptor-1 (PD-1) and T cell immunoglobulin and mucin-domain containing-3 (Tim-3) compared with unstimulated condition (CD8 alone) (figure 3B,C). Adding β ig-h3-depleting Abs decreased the percentage of cells expressing Tim-3 among CD8⁺CD44⁺PD-1⁺ cells in comparison with the percentage observed in the cocultures with control Ab-treated cells (figure 3C). Altogether, these results provide the first evidence indicating that β ig-h3 modulates antigen-specific antitumoural CD8⁺ T cell proliferation and activation *in vitro*.

β ig-h3 interacts with CD61 on the surface of T cells and F4/80 macrophages

β ig-h3 has been reported to induce signalling by binding to α v β 3 integrins.²⁷ We therefore evaluated the impact of r β ig-h3 on CD8⁺ OT1 cells and T cell signalling. We found that pretreatment with r β ig-h3 led to increased TGF β 1i1 (Hic-5) stabilisation on OVA stimulation (figure 4A). *Tgf β 1i1* codes for Hic-5 a member of the paxillin superfamily.^{28, 29} We found by immunoprecipitation experiments that Hic-5 bound to Y505-Lck was enriched in the context of β ig-h3 pretreatment (figure 4B). Furthermore, we analysed the expression of β 3 (CD61) on the surface of CD8⁺ T cells. We found that the CD8⁺ T cells present in tumours express CD61, and we further noted that

the expression of CD61 was significantly higher in tumour CD8⁺ T cells than in peripheral CD8⁺ T cells (figure 4C). We next sought to determine whether β ig-h3 signals through CD61 because treating CD8⁺ T cells with r β ig-h3 induced the internalisation of CD61 (figure 4C). As previously reported,¹⁷ treating CD8⁺ T cells with r β ig-h3 resulted in the phosphorylation of Lck at Y505, and furthermore, it colocalised with CD61 (figure 4C). These results show that β ig-h3 interacts with CD61 at the surface of CD8⁺ T cells and that this interaction induces the phosphorylation of Lck at Y505 and the subsequent inhibition of this early kinase of the TCR signalling pathway. We also found that F4/80 macrophages express high levels of CD61 (not shown). We used the Raw 264.7 macrophage cell line to stimulate with Phorbol myristate acetate (PMA) or PMA+r β ig-h3 and assessed for Hic-5 and pErk protein expression by Western blot. We found that Hic-5 was stabilised in the presence of r β ig-h3 and immunoprecipitated with Lck Y505 (figure 4D,E). More importantly, we found that macrophages cultured on collagen+r β ig-h3 layer had a diminished production of interferon gamma (IFN γ) and tumour necrosis factor-alpha (TNF α) than those cultured on collagen layer only (figure 4E,F). We confirmed our *in vitro* findings on FACS sorted CD8⁺ T cells and F4/80 macrophages from 2.5 months KC mice pancreata, cytopspined and stained for CD61, β ig-h3 and pERK. We found that CD61 colocalised with β ig-h3 and signalled through ERK in both cell types (figure 4F). These results suggest that β ig-h3 is able to modulate both CD8⁺ T cell and macrophage activation in the context of the pancreatic tumour.

CD8⁺ T cells are required for β ig-h3 effect *in vivo*

Because the *in vitro* depletion of β ig-h3 induced the activation and proliferation of CD8⁺ T cells, we next sought to investigate the role of β ig-h3 in modulating the host immune response during tumour growth. To explore this issue, we established an allograft system in which KC cell line (online supplementary table 1) was subcutaneously injected in C57BL/6 syngeneic mice (figure 5A). The injection of anti- β ig-h3-depleting Abs led to a significant decrease in both the size and weight of the tumours that developed in these mice (figure 5B,C). More importantly, we found that the number of EPCAM⁺/CD45⁺ neoplastic ductal cells was lower by FACS analysis (figure 5D). Furthermore, we found that lesions contained fewer cancer-initiating cells (defined as CD45⁺/CD44⁺/CD24⁺) in the mice injected with β ig-h3-depleting Ab (figure 5E). The depletion of β ig-h3 therefore led to the accumulation of CD8⁺ T cells (figure 5F), although the same percentages of recruited CD45⁺ and CD4⁺ T cells were detected (figure 5F and online supplementary figure S5). We also evaluated the impact of β ig-h3-depleting Abs on dendritic cells, Tregs, MDSC and macrophage populations within the tumours and found that there were fewer M2 CD206⁺ macrophages in the mice treated with the depleting Ab (online supplementary figure S5). It was previously reported that both the quantity and 'quality' of tumour-infiltrating CD8⁺ T cells are important.³⁰ Tumour-induced exhaustion is characterised by the expression of PD-1 on the surface of activated CD8⁺CD44⁺ T cells, and the expression of this marker was significantly lower in animals treated with anti- β ig-h3-depleting Abs than in control-treated animals (figure 5F). CD8⁺ T cells expressed more granzyme B, IFN γ and TNF α in the animals treated with anti- β ig-h3-depleting Abs than control animals (figure 5F). Furthermore, in Ag-specific B16OVA system neutralisation of the β ig-h3 protein led to increase specific OT1 producing IFN γ (online supplementary figure S5C). Altogether, our data show that the Ag-primed

Figure 5 β ig-h3 depletion increases the CD8⁺ T cell response. (A) Experimental setting. (B) Images of anti- β ig-h3-treated and ctrl Ab-implanted tumours. (C) Tumour weights. FACS analysis of the percentages of EPCAM⁺ CD45⁻ cells (D), CD44⁺CD24⁺CD45⁻ cells (E), CD45⁺CD8⁺ T cells and PD-1⁺CD44⁺ and granzyme B⁺, IFN γ ⁺, TNF α ⁺, CD107a⁺CD8⁺ T cells in implanted tumours (F). The results shown are representative of three independent experiments that included five mice per group. * $P < 0.05$ and ** $p < 0.01$.

CD8⁺ T cells infiltrating tumours in the absence of the β ig-h3 protein exhibited a less exhausted phenotype and more cytotoxic properties than in the control conditions, indicating that this protein plays a key role in the immunosuppression of the cytotoxic lymphocyte response.

To determine whether CD8⁺ T cells are required for the effect of β ig-h3 *in vivo*, we subcutaneously injected KC cell line that was treated with anti- β ig-h3-depleting or control Ab into immunodeficient Rag2^{KO} mice. The mice were then intravenously injected with CD8⁺ T cells that were isolated from the pancreatic-draining lymph nodes of KC mice (figure 6A). While mice injected with KC cells and pretreated with anti- β ig-h3-depleting Abs displayed a similar number of recruited CD45⁺ cells compared with

control mice (figure 6A), they exhibited a higher level of CD8⁺ T cells than that observed in the control animals (figure 6B). Moreover, concomitant with the increase in the number of CD8⁺ T cells, we detected a reduction in the proportion of neoplastic ductal CD45⁻/EPCAM⁺ cells (figure 6C). These results suggest that in the absence of β ig-h3 expression in the TME, CD8⁺ T cells accumulated within the tumour, and this phenomenon was responsible for the observed reduction in the proportion of EPCAM⁺ cells. One prediction based on these results would be that the observed reduction in the EPCAM⁺ population within the tumour could be rescued by depleting CD8⁺ T cells. To test this hypothesis, we subcutaneously implanted KC cell line in presence of anti- β ig-h3 depleting or control Abs into mice and

Figure 6 β ig-h3 depletion affects tumour growth in both early and advanced lesions. (A) Experimental setting. then depleted the mice of CD8⁺ T cells (figure 6D). These treatments resulted in the depletion of more than 90% of the CD8⁺ T cell population without altering the numbers of CD4⁺ T cells or F4/80 macrophages (online supplementary figure S6C,D). Although depleting CD8⁺ T cells did not affect the outgrowth of the implanted tumour, it did restore the tumour weight observed in the β ig-h3- depleted mice at similar level of that observed in the control animals (figure 6D). These findings suggest that β ig-h3 drives immunosuppressive TME, which inhibits T cell-mediated immune surveillance. In order to gain insight of the mechanism in advanced lesion, we injected subcutaneously KIC cell line (generated advanced lesion cell line, online supplementary figure S4B) into C57BL/6J mice in presence of control or depleting anti- β ig-h3 Ab (figure 6E–G, online supplementary figure S6E,F) in presence or absence of CD8⁺ T cells ($\pm$ CD8⁺ T cell-depleting Ab). We found that in absence of CD8⁺ T cells and β ig-h3 protein, there was an increase in F4/80 macrophages (figure 6F) and increased active caspase-3 staining (figure 6G).

β ig-h3 depletion increased immune-mediated tumour clearance *in vivo*

We next evaluated the therapeutic potential of targeting β ig-h3 in KPC and KIC mice, which are two well-established mouse models that develop aggressive PDA.^{21 23} Whereas the KIC mice were injected twice a week with anti- β ig-h3-depleting Ab for 21 days starting when the mice were 5 weeks old (online supplementary figure S7A,B), the KPC mice were subjected to the same when the tumourous volume was between 100 mm³ and 200 mm³ (figure 7A,B). Interestingly, both the KPC and KIC mice that were injected with anti- β ig-h3-depleting Abs had significantly smaller (approximately 38%–40%) tumourous volumes than were observed in the untreated animals (figure 7B, online supplementary figure S7B). The quantification of the tumourous area, which was assessed using CK19 staining, revealed that there was a drastic reduction in tumourous area, from 46% to 13%, in the lesions within the pancreas of the anti- β ig-h3-depleting Ab-treated animals than in the untreated mice (figure 7C,D). Moreover, the PanIN area was also significantly smaller in the β ig-h3-depleting Ab-treated animals than in the controls (figure 7C,D). The quantification of the number of cleaved-caspase-3⁺ cells showed that there were significantly more apoptotic cells in the anti- β ig-h3 Ab-treated mice than in the controls (figure 7E). More importantly, we detected an increase in the number of granzyme B-positive cells that were in close contact with cleaved-caspase-3⁺ cells in the anti- β ig-h3 Ab-treated animals (figure 7F). In order to find out if depletion of CD8⁺ T cells conjugated with anti- β ig-h3 treatment in advanced lesions restored tumour growth, we performed coinjections in KPC mice. We found that CD8⁺ T cell depletion was not able to restore tumour growth in the context of β ig-h3 depletion (online supplementary figure 7G). The tumour site displayed GrzB⁺ positive cells to similar extent to β ig-h3 depletion condition suggesting that other cells expressing granzyme B, that is, F4/80 macrophages (online supplementary figure S7H) might be involved. Moreover, since it was previously reported that β ig-h3 binds to collagens, we checked by atomic force microscopy (AFM) analysis the tissue rigidity and found that overall rigidity was reduced in anti- β ig-h3-treated mice (online supplementary figure S7D). These findings were corroborated with reduced collagen I thick fibres as determined in polarised light after Sirius Red staining, whereas the overall content of collagen was similar in untreated and Ab-treated animals (figure 7G,H). This stiffness release may have contributed to synergistic effect

observed in the combination therapy (anti- β ig-h3 and anti-PD-1 Abs) since this treatment led to further increased GrzB positive cells (online supplementary figure S7E,F) compared with anti- β ig-h3 depleting condition alone. Further investigations, should reveal the benefit of anti- β ig-h3 therapy in immune-excluded PDA tumour types.

DISCUSSION

The roles host immunity plays in regulating tumourigenesis and tumour progression are critical.³¹ However, immune cells within the TME fail to exert an effective antitumour immune response.³² This phenomenon is largely because an effective anti-tumoural immune response is unable to ‘reach’ the tumourous zone and is maintained ‘physically and functionally’ restricted to the surrounding microenvironment. In the TME, the stroma acts like a physical barrier that blocks access of both the immune system and chemotherapies to the tumour.³³ While depleting the stroma in mice by blocking Hedgehog signalling has been shown to exert beneficial effects,³⁴ subsequent clinical trials that targeted stromal myofibroblasts in human PDA actually accelerated disease progression, which resulted in these clinical trials being halted. Therefore, the underlying mechanisms that allow the stroma to modulate the immune response have not been fully characterised. Here, we show that the stromal matrix protein β ig-h3 directly restrains the anti-tumour immune response by inhibiting CD8⁺ T cell immunity in PDA. This strategy of immune evasion may therefore contribute to the resistance to immunotherapy that has been observed in this cancer.

PDA progression is associated with cellular and molecular changes in both the functional and stromal compartments of the pancreas. While lineage tracing experiments have shown that most preneoplastic lesions develop from pancreatic acinar cells via a process called acinar to ductal metaplasia,³⁵ little is known about how the stroma is modulated and what its contributions are during the early stages of pancreatic cancer. Here, we show that β ig-h3, a protein that was initially described as a secreted extracellular matrix protein that is produced mainly by fibroblasts, keratinocytes and muscle cells,³⁶ is a novel protein that affects the pathophysiology of PDA. Our data provide insights into the role of β ig-h3 in the modulation of the cellular interactions that occur in the TME during the early stages of PDA tumour development. While β ig-h3 is not expressed in the exocrine compartment of the normal murine or human pancreas, we found that its expression is substantially increased within the stroma during the early stages of PDA. Interestingly, overexpressing β ig-h3 in mice resulted in a higher incidence of spontaneous tumours than was observed in WT mice, whereas when β ig-h3 was knocked out, the resulting mice were comparable to WT controls.³⁷ These data suggest that targeting β ig-h3 might have no substantial side effects. We found that β ig-h3 was increased in patients with GI cancers, including oesophageal cancer, gastric cancer, hepatocarcinoma and PDA cancer.³⁷ In patients with oesophageal cancer, secreted β ig-h3 was detected in the stroma using immunohistochemistry. Patients with high levels of β ig-h3 in the stroma but not in tumour cells had a worse prognosis than those with low levels, indicating that this marker is a crucial contributor to a non-cell autonomous mechanism. Several lines of evidence indicate that β ig-h3 densely accumulates in the stroma of PDA, where it exerts an immunosuppressive effect. First, we used T cell proliferation assays (using either a recombinant molecule or secreted in CAF supernatants) and found that β ig-h3 exerted a suppressive effect by reducing antigen-specific activation and proliferation. Here, we provide the first evidence showing that the use of a depleting

Figure 7 $\beta\text{ig-h3}$ depletion in established PDA leads to reduced tumour volume. (A) Experimental protocol used for antibody depletion. (B) Tumoural volume was quantified using ultrasound (Vevo2100) in Ab-treated animals. (C) Representative immunohistochemistry for CK19 and cleaved caspase-3 in anti- $\beta\text{ig-h3}$ -treated (AB) and untreated (UT) KPC mice. Scale bar, 50 μm . Scale bar 50 μm . * $P < 0.05$, **** $p < 0.0001$. Ab, antibody; KC, $p48\text{-Cre}; Kras^{G12D}$; PDA, pancreatic ductal adenocarcinoma.

Ab against secreted β ig-h3 restored tumour-specific CD8⁺ T cell proliferation and activation and reduced cell exhaustion, which was measured using PD-1 and Tim-3 expression *in vitro*. Furthermore, β ig-h3 binds to and induces signals via integrin β 3 (CD61), which was highly expressed on infiltrating CD8⁺ T cells and led to increased Hic-5 protein binding to Y505 phosphorylated Lck blunting the signal transduction. Second, the depletion of β ig-h3 protein *in vivo* using an Ab strategy was accompanied by an increase in the GrzB⁺ response. In case of rapid aggressive lesion development, the combination therapy with anti-PD-1 Ab had a synergistic effect (KIC mice). Third, the immune-mediated elimination of subcutaneously injected tumour cells was fully rescued by CD8⁺ T cell depletion, indicating that the β ig-h3 protein plays a central role in disrupting an effective antitumoural response during the early stages of neoplasia. Considering the limitation of using 'ex vivo' generated KC line in subcutaneously injected recipients setups, we reinforced the relevance of this immune modulatory mechanism in already established PDA and found out that the TME was reprogrammed raising the exciting possibility that targeting β ig-h3 may bolster immune-mediated antitumour efficacy in patients.

What drives the production of β ig-h3 within tumours? β ig-h3 was first isolated from the A549 human lung adenocarcinoma cells that were treated with TGF- β .¹⁰ Its expression is regulated by TGF- β in addition to other factors and mechanisms, including autophagy, microRNAs, interleukin (IL)-1 and IL-4.³⁸ TGF- β is highly expressed in several cancers, including PDA, and has been associated with tumour progression.³⁹ In our experiments, TGF- β increased the production of β ig-h3 by CAFs. The molecular mechanisms responsible for the selective increase in β ig-h3 levels within the stroma but not in the ductal tumourous compartment remain to be identified.

The critical role of CD8⁺ T cells in tumour clearance is undisputed. CD8⁺ T cell tumour infiltration is thought to indicate a good prognosis.⁷ A previous study showed that endogenous CD8⁺ T cells are relatively sparse in PDA.⁴⁰ Moreover, a recent study showed that long-term survivors PDA patients have infiltrating CD8⁺ T cell and neoantigens.⁸ In addition to the decrease in their numbers, CD8⁺ T cells in the TME also fail to mount an effective antitumour immune response.³² Our study reinforces the notion that CD8⁺ T cells are 'reprogrammed' by powerful antitumour factors. Whereas depleting CD8⁺ T cells did not accelerate tumour progression in the presence of β ig-h3, it completely abolished the benefit conferred by β ig-h3 neutralisation in the context of the 'early' lesions (KC model). In 'advanced' lesions (KIC and KPC model), we found that depletion of β ig-h3 reprogrammes the TME in absence of CD8⁺ T cells. This observation supports previous studies that showed that $\alpha\beta$ T cells are entirely dispensable in PDA but can be 'reprogrammed' in efficient antitumour cells by modulating the TME by either depleting $\gamma\delta$ T cells⁴¹ or targeting focal adhesion kinase, which is an important regulator of the fibrotic and immunosuppressive microenvironment.⁴² We show here for the first time that the depletion of β ig-h3 led to reduced tumour tension within the TME without modifying the overall content of collagen but rather the fibre thickness that has been previously shown to be associated with good prognosis in patients with PDA.⁴³ These physical and functional modifications led to the 'reprogramming' of the TME by instructing F4/80 macrophages to secrete inflammatory and cytotoxic molecules. Furthermore, we identified Hic-5 to be associated with the phenotypical and functional changes of both CD8⁺ T cells and F4/80 macrophages. Hic-5 has been recently identified as a crucial sensor of ECM remodelling by promoting fibrillar adhesion formation.⁴⁴

Another very interesting finding is that using a β ig-h3-depleting Ab reduced the number of cancer-initiating cells (CD45⁺CD44⁺CD24⁺). Cancer-initiating cells are known to express a variety of molecules that are associated with their 'stemness' and that may potentially be recognised by the immune system as tumour antigens.⁴⁵ These findings suggest that CD8⁺ T cells play a potential role in this mechanism because the recognition of tumour Ag by CD8⁺ T cells initiates the elimination of those cells. Since cancer-initiating cells have been hypothesised to be responsible for metastasis in PDA⁴⁶ and to be resistant to conventional chemotherapy and radiation therapy,⁴⁷ the usefulness of β ig-h3-depleting therapies might extend beyond the targeting primary tumours.

Using immunotherapy to reactivate antitumour immunity has delivered promising results in several tumour types⁴⁸ but not in pancreatic cancer. Our results indicate that a promising novel opportunity to achieve this objective may be the use of depleting Abs against β ig-h3 even in the context of immune-excluded patients with PDA. Our findings support the potential use of β ig-h3 as a target in PDA treatments aimed at restoring beneficial antitumour immunity. As an extracellular and therefore potentially accessible and targetable protein, β ig-h3 may indeed have high clinical value for diagnosing and treating PDA.

METHODS

Mice

The KC, KIC and KPC mice have been previously described.^{21 23 49} OT1/Rag2^{KO} transgenic mice expressing the T cell receptor were used as the source of the CD8⁺ T cells that were used in the *in vitro* experiments.⁵⁰ Rag2^{KO} and C57BL/6 mice were obtained from The Charles River Laboratories and used as the hosts in the subcutaneous tumour implantation experiments. All animal protocols were reviewed and approved in accordance with the guidelines provided by the Cancer Research Center Lyon Animal Care and Use Committee.

Collection of tissue samples from mice

Normal and tumourous pancreas were washed in phosphate buffered saline (PBS), minced into small fragments and then incubated in collagenase solution (1 mg/mL collagenase V obtained from Roche in HBSS) at 37°C for 20 min. The spleen and peripancreatic lymph nodes were homogenised and passed through a 70 μ m cell strainer to achieve single cell suspensions. Red blood cells were lysed using NH₄Cl lysis buffer.

Antibodies

The following monoclonal Abs were used in flow cytometry: anti-CD45 (30-11, APC-Cy7, PE), anti-CD8 (Ly-2, V450), anti-CD4 (RM4-5, V500) anti-CD44 (IM7, Alexa 700) anti-mouse OVA257-264 (SIINFEKL) peptide bound to H-2Kb (PE), anti-CD326 (EPCAM) (9C4; FITC), anti-CD24 (30-F1, PE-Cy7), anti-CD69 (H1.2F3, PerCP/Cy5.5), anti-CD61 (Ebioscience, 2C9.G3; FITC) anti-PDGRF α CD140 α (Abcam, 16A1; PE); anti-Ly6C PE, anti-Ly6G BV785, anti-Foxp3 Alexa 488, anti-F4/80 Pe-Cy7, anti-CD206 BV650, anti-CD11b Percp Cy5, anti-CD86 BV605, anti-CD80 APC-Cy7, anti-IFN γ BV650, anti-GrzB Alexa647, anti-TNF α BV605, anti-NKp46 Alexa 488, anti-CD107a Pe-Cy7, anti-CD29 Percp Cy5, anti-PD-1 PE, anti-Tim3 APC, anti-Lag3 Percp Cy5 and anti-CD11c Alexa 700 (all from Biolegend). The flow cytometry analyses were performed using a BD Fortessa Flow Cytometer (BD Biosciences) and analysed using either BD FACS Diva software V.5.0.1 (BD) or FlowJo (Tree Star). For the *in vivo* studies, the following endotoxin-free Abs

were used: anti-CD8 (BioXcell; 2.43), anti- β ig-h3 18B3,⁵¹ anti-PD-1 and control polyclonal mouse Ig (BioXcell).

Isolation of pancreas cell populations

Ductal cells and CAFs were isolated using anti-CD45, anti-PDGFR α -PE and anti-EPCAM or CD45, CD8 and F4/80 and CD3 Abs and FACS sorting.

Cell lines

The isolation and culture of KC and KIC mouse cells were performed using a protocol adapted from a previously published.²⁶ Cells were obtained from the pancreas of 2.5-month-old KC or KIC mice and dissociated. The cells were then plated in 6-well plates with serum-free Dulbecco's Modified Eagle Medium (DMEN). After 2 weeks, the media was changed to DMEN+10%FCS. After three to six passages, the cells were used in experiments. The phenotypes are described in table 1. Alternatively, mitomycin-treated KC cells were used to stimulate T cells that were derived from the pancreatic lymph nodes of KC mice. PDGFR α -PE isolated CAF (obtained from three different KC mice) were cultured and amplified in vitro. CAF or ductal cells were seeded at 10^4 cells/well and then stimulated using mouse TGF- β 1 at a final concentration of 20 ng/mL for 48 hours. The CAF supernatants (CAF SNs) were then collected and used in the T cell suppression assays.

Functional T cell suppression assay

Purified CD8⁺ T cells were labelled with 1 μ M CFSE (Invitrogen) at 37°C for 20 min in serum-free RPMI. OT1 CFSE-labelled splenocytes were stimulated with OVA (SIINFEKL) peptide for 5 days in the presence or absence of recombinant human β ig-h3 (r β ig-h3) at a final concentration of 5 μ g/mL. The antigen-specific suppression of CD8⁺ T cells was evaluated in coculture assays in which splenocytes obtained from OT-1 transgenic mice (antigen-specific assays) were seeded in triplicate in 96-well round bottom plates (5×10^5 cells/well). The splenocytes were cultured in the presence of CAF SN that was treated with or without anti- β ig-h3 Ab and then stimulated with a cognate antigen, the OVA-derived peptide SIINFEKL (1 mg/mL; New England Peptide) for 3 days. Alternatively, mitomycin-treated KC cells were cocultured with CFSE-labelled pancreatic lymph node cells in the presence of a depleting anti- β ig-h3 Ab or control Ab (BioXcell, USA) at a final concentration of 6 μ g/mL for 5 days. Proliferation was evaluated at the end of the culture period using flow cytometry for CFSE dilution.

Macrophage assay

Raw 264.7 mouse macrophage cell line was used for phagocytosis assay. The cells were treated with PMA or PMA+r β ig-h3 for 24 hours, and the cells were recovered and assessed for FACS staining, western blot and immunoprecipitation analysis. Alternatively, raw 264.7 cells were treated with PMA for 24 hours and seeded on collagen or on collagen+r β ig-h3 layers for 48 hours and further assessed for cytokines production by FACS staining.

Short-term KC and KIC implantation studies

KC or KIC cells (5×10^5) were subcutaneously injected with an anti- β ig-h3 depleting Ab (6 μ g) or isotype control Ab (6 μ g, BioXcell) and were embedded as plugs in a Matrigel 1:1 mix (Corning) into the flanks of normal C57BL6 or Rag2^{KO} mice. The mice were then monitored for 10 or 14 days and then sacrificed at the indicated time points. The tumour grafts were then weighed, measured and processed for staining prior to flow cytometry.

CD8⁺ T cells were depleted in vivo by injecting the mice with two consecutive intraperitoneal injections of anti-CD8 mAbs (BioXcell, 16 μ g/mouse) at the indicated time points. To deplete β ig-h3 in KC mice, the mice were intraperitoneally injected with an anti- β ig-h3 depleting monoclonal Ab⁵¹ or a control monoclonal Ab (BioXcell, USA) at a concentration of 300 μ g/kg once per week for 4 weeks. Alternatively, purified CD8⁺ (10^6) T cells were obtained from the pancreas-draining lymph nodes of KC mice and intravenously transferred into Rag2^{KO} recipients that were implanted with KC tumours. B16OVA cell line was also used in subcutaneous injection together with intravenous injection of OT1 cell in Rag2^{KO} recipient mice.

Treatment of KPC and KIC mice

KPC or KIC mice were treated twice a week for a period of 21 day and the sacrificed. Tumour volume monitoring was done by VevoScan in KPC mice. β ig-h3 was used at 8 μ g/mouse and anti-PD-1 20 μ g/mouse. For combo, the injections were done separately in ip at the same time (twice a week).

Immunofluorescence analysis of intratumoural CD8⁺ T cells

CD8⁺ T cells and F4/80 macrophages were FACS sorted (>98%) from the pancreata of KC mice using a BD FACSAria flow cytometer. Cytospin preparations were fixed in 0.4% paraformaldehyde for 10 min and then permeabilised in 0.1% Triton X-100 for 10 min. The cells were washed in PBS/0.05% Tween and then blocked with Ab diluent (Dako) for 15 min before they were stained overnight at 4°C with CD61 (Ebioscience; 2C9. G3; FITC) pY505 (Cell Signaling) Abs, pERK and β ig-h3 Ab. The slides were then incubated with specific anti-Fab'-Alexa 647 and anti-Fab'-Alexa 555 (Molecular Probes) and mounted in Vectashield mounting medium with DAPI. Representative images of the pattern of localisation of each molecule are shown. All confocal analyses were repeated multiple times, and at least 20 images were analysed for each molecule. The method used to quantify the results of the colocalisation analysis was previously described.⁵² The data were rendered and analysed using Zen software (Zeiss).

Biological resources

Slides with pancreatic tissues obtained from patients with PDAC were collected from the La Timone and Edouard Herriot Hospitals. Paraffin-embedded pancreatic tissues (5 μ m thick sections) were stained using immunohistochemistry and immunofluorescence. All experimental procedures were approved by the French National Ethics Committee.

Immunohistochemistry and immunofluorescence

Slides with 4 μ m thick sections of mouse or human pancreatic tissues embedded in paraffin were deparaffinised. The sections were unmasked using unmasking solution (Vector H 3300), saturated with Ab diluent (Dako) for 30 min and then incubated with primary Abs (anti- β ig-h3, Sigma; anti-caspase-3, Cell Signaling; and CK19 Troma III, DSHB) that were diluted in Ab diluent overnight at 4°C. The sections were washed and then incubated with goat antirat biotinylated secondary Abs (BD Biosciences; 1:200) for 1 hour at RT. The remaining steps were performed using Vectastain ABC kits (Vector Labs). The slides were counterstained with hematoxylin. Alternatively, immunofluorescence was performed using deparaffinised and unmasked sections, which were incubated in anti- β ig-h3, anti-PDGFR α , anti-EPCAM, anti-GrzB and anti-Casp3 primary Abs overnight at 4°C and then with specific anti-Fab'-Alexa 647 and anti-Fab

' 2-Alexa 555 (Molecular Probes) secondary Abs. Finally, the sections were mounted in Vectashield mounting medium with DAPI.

RT and qPCR

RNA was extracted using a Qiagen kit from pelleted islets according to the manufacturer's instructions. RNA concentrations were measured using a Nanodrop spectrophotometer. RT was assessed using equivalent quantities of extracted RNAs (superior to 300 ng). cDNA was used to perform quantitative polymerase chain reaction (qPCR) analyses with Power SYBR Master Mix (Life Technologies). The following primers were used: TBP Forward 5'-TGGTGTGCACAGGAGCCAAG-3', TBP Reverse 5'-TTCACATCACAGCTCCCCAC and β g-h3 all-in-one qPCR (MQP028379) primers, which were obtained from GeneCopoeia.

Western blot and immunoprecipitation

For western blot analysis, 30 μ g of protein was loaded on the gel, then separated by 12% SDS-PAGE (Biorad) and transferred to a Hybond nitrocellulose membrane (Amersham Pharmacia Biotech). After transfer, the immunoblots were blocked by incubating with 5% BSA in Tris-buffered saline and 0.1% Tween 20. Next, the blots were probed overnight with the appropriate dilution of the primary Abs (anti-Lck, anti-pSrc pY416 which recognises Lck on pY394, anti-pLck pY505, anti-phospho ERK1/2 from Cell Signaling, anti-Hic-5 Ab from BD Biosciences, anti- α tubulin from Genetex) and revealed with either HRP-conjugated sheep antimouse or HRP-conjugated antirabbit Ab (Amersham, Pharmacia Biotech) for 1 hour at room temperature. After washing, the blots were developed using the ECL chemiluminescence method (Pierce Chemical) according to the manufacturer's protocol. For band intensity quantification, ImageLab was used. For immunoprecipitation 500 μ g of total protein were incubated with 1 μ g of anti-pLck pY505 overnight at 4°C. pLck-associated proteins were then precipitated with protein A-Sepharose (Sigma-Aldrich) for 1 hour at 4°C. The sepharose beads were spun down, washed, resuspended in SDS-gel sample buffer and boiled at 95°C for 3 min. Immunoprecipitates were separated by 12% SDS-PAGE and immunoblotted for Hic-5.

Atomic force microscopy

We used AFM coupled with confocal microscopy to determine sequentially mechanical properties and pancreatic tissue domain identity. In AFM, the tip of a cantilever is pushed against the sample, and the deflection of this cantilever is monitored. Using the stiffness constant of the lever, the deflection indicates the resisting force of the sample. Our protocol⁵³ allows us to measure the stiffness of sample very locally in a minimally invasive manner, by deforming the sample down to a depth of 100 nm. In order to investigate the stiffness patterns and the different domains of the pancreatic exocrine compartment during PDA (stromal compartment and pancreatic tumour cells) at high resolution we used the quantitative nanomechanical mapping and the force volume protocols (Bruker). In these protocols, the AFM probe oscillates at low frequency while horizontally scanning the sample and a force curve in generated each time the probe made contact with the sample. The elastic modulus of sample, reflecting the stiffness, is then extracted from each curve applying the Sneddon (Hertz) model, yielding two-dimensional stiffness maps, where each pixel represents one force curve.

Statistical analysis

P values were calculated using Student's t-test, (GraphPad Prism) as indicated in the figure legends. *P<0.05; **p<0.01;

P<0.001; and *p<0.0001. For multiple comparisons, one-way analysis of variance with Tukey's post hoc test was used.
