ABSTRACT
Objective The gut microbiota has been proposed as an interesting therapeutic target for metabolic disorders. Inulin as a prebiotic has been shown to lessen obesity and related diseases. The aim of the current study was to investigate whether preintervention gut microbiota characteristics determine the physiological response to inulin.

Design The stools from four obese donors differing by microbial diversity and composition were sampled before the dietary intervention and inoculated to antibiotic-pretreated mice (hum-ob mice; humanised obese mice). Hum-ob mice were fed with a high-fat diet and treated with inulin. Metabolic and microbiota changes on inulin treatment in hum-ob mice were compared with those obtained in a cohort of obese individuals supplemented with inulin for 3 months.

Results We show that hum-ob mice colonised with the faecal microbiota from different obese individuals differentially respond to inulin supplementation on a high-fat diet. Among several bacterial genera, Barnesiella, Bilophila, Butyricimonas, Victivallis, Clostridium XIVa, Akkermansia, Raoultella and Blautia correlated with the observed metabolic outcomes (decrease in adiposity and hepatic steatosis) in hum-ob mice. In addition, obese individuals, the preintervention levels of Anaerostipes, Akkermansia and Butyricoccus drive the decrease of body mass index in response to inulin.

Conclusion These findings support that characterising the gut microbiota prior to nutritional intervention with prebiotics is important to increase the positive outcome in the context of obesity and metabolic disorders.

INTRODUCTION
The interaction between nutrients and the gut microbes is involved in the regulation of host metabolism, namely in the context of obesity and related metabolic diseases. One interesting strategy to envisage weight control is the elaboration of nutritional interventions/recommendations with dietary fibres considered as prebiotics, defined as ‘substrates that are selectively utilized by host microorganisms conferring a health benefit’. The administration of inulin as prebiotic reduces adiposity and obesity-associated metabolic disorders in preclinical and human studies. Gut microbiota modulation by inulin-type fructans differ between individuals following the pattern of dietary fibre intake. However, in view of the existing data, it is difficult to evaluate which changes in the gut...
microbiota driven by inulin are involved in the improvement of obesity and metabolism in humans.9–14 Gut microbiota characteristics explain the variable response toward several dietary interventions. Indeed, the initial gut microbiota influences the glycaemic response to real-life meals or bread as well as microbiota changes on resistant starch supplementation.15–17 A recent study highlighted that similar foods induced different effects on microbiome, suggesting that the interactions between diet and microbiome are personalised.18

In this context, we tested the hypothesis that the preintervention gut microbiota composition could influence the metabolic and microbial response to inulin supplementation in obese subjects. Faecal material was taken from obese individuals prior to intervention and transferred into microbiota-depleted mice (hum-ob for humanised obese mice). The metabolic and microbial response of hum-ob high-fat diet (HFD)-fed mice toward inulin supplementation was evaluated and compared with the response to inulin intervention in obese patients. We also analysed the preintervention characteristics of the gut microbiota that drive the improvement of body weight in obese patients treated with inulin (ClinicalTrial.gov identifier: NCT03852069).

METHODS
Additional protocols and complete procedures are described in the online supplementary material and methods section.

Experimental model and subject details
Mice
Specific pathogen-free (SPF) C57BL/6J male mice (Janvier Labs, Le Genest St Isle, France) were housed in a controlled environment (three per cage, 12 hours daylight cycle) with free access to food and water. Young mice (aged 4 weeks) were used to optimise the gut microbiota engraftment.19 Mice were divided into nine groups: one control group (SPF) and eight groups of mice inoculated with the faecal material of obese patients (hum-ob, figure 1A). According to previous procedures,19 20 the intestinal microbiota was first depleted by antibiotic treatment and cleansing with polyethylene glycol (PEG). Stool samples from four obese patients were inoculated three times (one time per day every 2 days). Control mice received water by gavage at the same time. After the first inoculation with stool samples, all groups of mice including the control mice were fed a HFD (45% kcal fat; E15744-347, ssniff, Soest, Germany) for 4 weeks. For each donor, one subgroup was supplemented with 0.2 g/day per mouse of native inulin (Fibroline, Cosucra, Pecq, Belgium) in the drinking water for 4 weeks.

Metabolic measurements
Plasma insulin and glucose were measured. The subcutaneous adipose tissue (SAT) was stained with H&E for adipocyte size quantification. Liver lipids were stained with oil red O; lipids were extracted from muscle gastrocnemius and liver prior enzymatic quantification. Protein extraction and immunoblotting of protein of interest were performed in liver and gastrocnemius muscle. Total RNA was isolated from different sections of SAT, brown adipose tissue (BAT), liver and skeletal muscle prior reverse transcriptase quantitative PCR (qPCR) analysis.21 The full procedures are detailed in online supplementary information.

Human cohort
The clinical intervention consisted of a 3-month, multicentric, single-blind, placebo-controlled randomised intervention in male and female obese patients (see online supplementary section for inclusion and exclusion criteria). One hundred and six patients were randomised to receive either 16 g/day of native inulin (Cosucra, Belgium) or 16 g/day of maltodextrin (Cargill, Belgium). Fifty-five patients were randomised in the placebo group and 51 patients were assigned to the inulin group. Written informed consent was obtained from all participants before inclusion in the study.

Statistical analysis
Mice experiments: One-way analysis of variance (ANOVA) was performed between the SPF group and humanised untreated mice to evaluate the effect of faecal microbiota transfer (FMT), followed by a Tukey post hoc test. Effect of inulin supplementation was assessed using a Student’s t-test between the two groups of mice colonised with the same donor.

Microbiota analysis: Significantly affected taxa or amplicon sequence variants (ASVs) by inulin were identified using a Welch’s t-test in R, between untreated and treated groups for each donor. The p-value of the Welch’s t-test was adjusted (q-value, significant if q<0.05) to control for the false discovery rate (FDR) for multiple tests according to the Benjamini and Hochberg procedure.22 Correlation between the variation of genera or ASVs significantly regulated by inulin and other metabolic variables was assessed by Spearman’s correlation tests with an FDR correction. A significance level of q<0.05 (adjusted p-value) was adopted for all analyses.

Human cohort: Responders and non-responders to inulin treatment were discriminated according to the body mass index (BMI) median value. Principal component analysis (PCA) and partial least square discriminant analysis (PLS-DA) models were built based on selected variables in R. For PLS-DA, a loading >0.35 was chosen.

RESULTS
Characterisation of mice microbiota after FMT
We first selected four donors from the cohort of obese patients prior inulin intervention, who differed by the gut microbiota composition to perform FMT in antibiotic-PEG pretreated mice (figure 1A). Antibiotic-PEG efficiency was confirmed by the drastic decrease in total bacteria, supporting the elimination of more than 99.8% of faecal bacteria (figure 1B,C). Except for the SPF control group, all mice were recolonised by FMT with stools of obese patients. Donors were obese, drug-naive diabetic or non-diabetic, displaying different faecal bacterial gene richness (Chao1 index, figure 1D) and differences in gut microbiota composition at the family level (figure 1E). The metabolic features also differed between donors, despite a similar BMI, as shown in online supplementary table 1. Four weeks after the FMT, similarities between the caecal microbiota of recipient mice and faecal microbiota composition of their respective donors were assessed. Unweighted UniFrac distance confirmed a different distribution between SPF and hum-ob mice (figure 1F). hum-ob mice gut microbiota being very close to their respective donors. Moreover, the level of Faecalibacterium prausnitzii, bacteria that are present in high proportion in humans but minimally in mice, clearly increased in all hum-ob mice, confirming that human bacteria colonised the recipient mice (figure 1G).

Differential response to inulin on body weight and adiposity in hum-ob mice
Despite similar food, water and inulin intake between groups (online supplementary figure 1A–C), the response to HFD in
Figure 1  FMT from obese donors into antibiotic-pretreated mice. (A) Experimental design. (B and C) Total faecal bacteria analysed by qPCR in DNA extracted from faeces of antibiotic-treated mice at different time points (D0: before treatment, D4, D8: 4 or 8 days of antibiotic treatment). (B) Represents number of cells per gram of faeces. (C) Represents percentage of total faecal bacteria compared with D0. Results are expressed as mean±SEM. (D) α-diversity is estimated using the chao-1 index in the entire cohort, at baseline. Donors selected for FMT are represented by circles coloured red, green, orange and blue corresponding to donors 1, 2, 3 and 4, respectively. (E) Barplots for relative abundance of family levels accounting for more than 1% for each donor. (F) Principal coordinate analysis of the β-diversity index Unweighted UniFrac, coloured by mouse group. Small circles represent individual mice and larger circles represent human donors (D1, D2, D3, D4 for mice samples and H1, H2, H3, H4 for their respective human donor samples). Inulin decreases hepatic lipid accumulation in D1 and D4 hum-ob mice

Inulin reduced lipid (triglyceride and cholesterol) accumulation only in D1 and D4 hum-ob (figure 3A-D). D1 mice had increased acetyl CoA carboxylase (ACC) phosphorylation on serine 79 residue, an effect further promoted by inulin and signing AMP-activated protein kinase (AMPK) activation (figure 3E). Inulin also decreased nuclear sterol-regulatory element-binding proteins 1c and 2 (Srebp-1c and Srebp-2) in D1 and D4 mice (figure 3F,G). In D1 mice, inulin reduced cd36 and pparge1a mRNA, two proteins involved in FA uptake and oxidation (figure 3H), and mRNA levels of markers controlling triglycerides synthesis, such as acaca, scd1, dgat2 and elov13 (figure 3H; online supplemental table 2). Inulin also decreased scd1 and dgat2 mRNA in D4 mice. These data suggest that inulin reduces hepatic lipid content in D1 and D4 mice by regulating the expression of genes involved in lipogenesis and FA oxidation.

Inulin improves muscle insulin sensitivity in D1 hum-ob mice

Biochemical analysis of gastrocnemius skeletal muscle highlighted an increase of intramuscular lipid and triglyceride content only in D1 hum-ob mice compared with SPF control mice, which was abrogated by inulin (figure 4A,B). In line with these findings, inulin robustly increased the phosphorylation of both protein kinase B, Akt (serine 473) and mammalian target of rapamycin, mTOR (serine 2448) in D1 hum-ob mice, indicating insulin signalling stimulation (figure 4C,D). As in the liver, inulin decreased cd36 mRNA expression in the soleus of D1 mice. Pparg mRNA was increased in D1 muscle and decreased by inulin in both D1 and D4 hum-ob mice (figure 4E; online supplemental table 2). Cpt1b mRNA increase in hum-ob mice was counteracted by inulin in D1 mice only (figure 4E). Those data support that inulin improves insulin sensitivity in the muscle of D1 mice by decreasing FA uptake, limiting the availability of ligands of PPARg (peroxisome proliferator-activated receptor gamma). Notwithstanding these effects, we did not observe significant changes in fasting glycemia and insulinemia with the treatment (online supplementary figure 1D,E).

Inulin does not alter overall microbiota composition but induces donor-specific changes in microbiota composition

Caecal content and tissue weights were increased by inulin in all groups, signing a similar inulin fermentation (figure 5A,B). FMT decreased microbial α-diversity (Chao1 and Shannon indices) in all hum-ob mice, compared with control mice (figure 5C,D). Evenness dropped further with inulin in D2 and D4 mice. Unweighted UniFrac distance showed clusters due to interpersonal variation between donors (figure 5F). Univariate analyses revealed that inulin induced donor-specific effects at the phylum and family level in hum-ob mice (figure 5E; online supplementary table S3). We also identified a subset of 18 genera differently regulated by inulin (FDR correction, q value <0.05), depending on the donor. Inulin increased Bifidobacterium and decreased Barnesiella, Butyricimonas, Bilophila, Hungatella and Victivallis in D1 mice (online supplemental table S4). In D2 mice, Alstipes, Coprobacter and Parabacteroides decreased with inulin, whereas Bacteroides increased. In D3 mice, inulin decreased Paraprevotella and Murimonas. In D4, inulin increased Parabacteroidetes, Clostridium XIVa, Raoultella, Blautia and Akkermansia and decreased Bacteroidetes, Clostridium XVIII and Oscillibacter. In addition, the analysis of ASVs showed that the most abundant ASV and related genera are similarly regulated by inulin (online supplemental table S4). In addition, three ASVs belonging to Ruminococcus 2, Parasutterella and Collinsella, respectively, were decreased by inulin in D2 mice and one ASV from Desulfuromonas genus decreased with inulin in D3 group (online supplemental table S5). Forty other ASVs not be classified at the genus level were modified by inulin, including one ASV from Enterobacteriaceae family that largely decreased on inulin in all hum-ob mice (ASV12; online supplemental table S5). Highly abundant ASV5 from Firmicutes and the unclassified ASV7 also dramatically decreased on inulin treatment in some hum-ob mice.

Some specific bacteria, known to be regulated by inulin, were also quantified by qPCR. FMT clearly decreased the level of Lactobacillus spp and increased Faecalibacterium spp in all hum-ob mice (online supplemental figure 2D,E). Inulin increased total bacteria and Bifidobacterium spp in D1 and D4 groups (online supplemental figure 2A,B). Roseburia spp was increased by inulin in all hum-ob mice (online supplemental figure 2C). Finally, inulin specifically raised the levels of Faecalibacterium spp, Lactobacillus spp and Akkermansia muciniphila in D4 mice (online supplemental figure 2D-F).

Correlation analysis between the most significant metabolic effects and the 18 genera regulated by inulin was performed. Among several correlations identified (q-value <0.05), some genera positively correlated with hepatic lipid accumulation (Barnesiella, Butyricimonas, Bilophila, Hungatella and Victivallis) and are those significantly decreased by inulin in D1 mice, the group exhibiting the better metabolic response to inulin (figure 5; online supplementary table S4). Moreover, the four genera negatively correlated with hepatic lipid content (Clostridium XIVa, Raoultella, Blautia and Akkermansia) were specifically increased in D4 mice, the second inulin-responder group of mice. Correlation analysis was also performed between biological parameters and all ASVs modulated by inulin and belonging to other genera or unclassified as genus. ASV218 from Desulfuromonas negatively correlated with cd36 level in SAT (online supplementary figure 3). The other unclassified ASVs correlated with metabolic features were not similarly regulated by inulin in D1 and D4 groups. Only the ASV12 was regulated in all hum-ob mice but did not correlate with biological parameters (online supplemental table S5 and online supplementary figure 3).

Microbiota-related criteria drive the metabolic response to inulin treatment in hum-ob mice and in humans

The model of FMT in mice did not allow to identify the bacteria that could be implicated in body weight changes. For this, we used the whole human cohort of obese patients treated with inulin, to verify whether some bacteria could be linked to the BMI regulation by inulin.

Donors used for FMT have been enrolled in a large clinical intervention on the impact of 3-month inulin supplementation (16g/day) in obese patients, combined with dietary advice to consume vegetables enriched in inulin-type fructans. The impact of inulin treatment in donors was consistent with the response in hum-ob mice: donor 1 had better clinical measures after inulin, including decreased BMI and fat mass, improved hepatic steatosis.
and decreased energy intake (table 1). For donors 2 and 3, despite a loss of 3–4 kg, no metabolic or anthropometric changes were observed. Surprisingly, for donor 4, the effect of inulin differed from the *hum-ob* mice since inulin did not improve fat mass or hepatic lipid accumulation (table 1). Actually, donor 4 largely increased her energy intake as lipids and carbohydrates, and reduced her physical activity during the intervention. This probably explains the different impact of inulin between mice and donor.

At the end of the intervention, we subdivided participants in the inulin arm (n = 51), according to the median of the BMI change into non-responders (unchanged BMI) and responders (decreased BMI; figure 6A). Chao1 index, reflecting the richness of the gut microbiota, was similar between non-responder and responder groups (figure 6B). Surprisingly, PCA using the variation (difference between baseline and 3-month intervention) of all bacterial genera during the clinical intervention did not allow to separate non-responders and responders (figure 6C). Interestingly, the PCA taking into account only the variation of genera with inulin highlighted in *hum-ob* mice (ie, 18 genera identified by taxonomic analysis + 4 with ASV analysis) tended to separate non-responder and responder groups (Monte Carlo test, p = 0.06, figure 6D). The PLS-DA, based on the variation of the same subset of genera (identified in mice) during the human protocol, indicated that the main variations responsible for the different BMI response seem to be the increase in *Bifidobacterium, Akkermansia, Bacteroides* and other new genera such as *Butyricicoccus* that seems highly present in responders (figure 6G). Univariate analysis only show a significant higher basal presence of *Akkermansia* and *Butyricicoccus* and a lower level of *Anaerostipes* in responders, compared with non-responders. These data support that a subset of bacteria involved in the specific response to inulin probably plays an important role in the interindividual response in terms of BMI observed in the human cohort.

**DISCUSSION**

Inulin-type fructans have been proposed as an interesting dietary fibre with prebiotics properties, since many animal data and some intervention studies with inulin support their potential interest in the management of body weight and obesity-related diseases. The link with the gut microbiota changes occurring on inulin intervention remains elusive. A previous study demonstrated that short-chain fructans decreased the body weight gain, fat mass accumulation and increased caecal content in axenic mice inoculated with stools from one healthy lean adult. The authors propose that the results may depend on the human gut microbiota used for the inoculation and may not be generalisable. We show in our study that the inulin response is highly variable across ‘humanised’ mice colonised with the stools from different obese patients, providing evidence that the gut microbiota composition prior to intervention influences the health outcome. For this, we inoculated mice with samples from different obese donors, and body weight gain of *hum-ob* mice on HFD was differently affected by inulin, even when mice...
Figure 6  Intervention study with inulin in a multicentric human cohort reveals inulin responders (R) and non-responders (NR) in term of body mass index (BMI) improvement and changes in the gut microbiota. (A) Variation of BMI, after 3 months of intervention, in the inulin arm: NR (n=26) and R (n=25) patients were separated using the median change in BMI. ** p<0.001 versus placebo and $$$ p<0.001 versus NR. (B) Chao1 index (alpha-diversity) in NR (n=23) and R (n=24). (C–D) Principal component analysis of the gut microbiota composition based on all the genera (C) or selected genera (D) in NR and R patients. Statistical analysis was assessed by a Monte Carlo rank test. (E) Partial least square discriminant analysis (PLS-DA) of the variation of selected genera (selection from the humanised obese mice (hum-ob) mice model) during the intervention with inulin in NR and R patients. (F) Variation of the most discriminant genera after 3 months of intervention. Data are expressed as mean±SEM and analysed with a Mann-Whitney test in R compared with NR subjects. (G) PLS-DA of all genera, before the intervention, in NR and R patients. The main variables (cut-off: 0.1% of relative abundance, loadings >0.35) explaining the clustering are represented. (H) Relative abundance of bacterial genera, at baseline, selected (by the previous PLS-DA and the in vivo model of hum-ob mice) in NR and R patients. Data are expressed as mean±SEM and analysed with a Mann-Whitney test in R compared with NR subjects.
exhibit the same dietary behaviour. Inulin differently regulated metabolic changes in adipose tissues, liver and skeletal muscle. Finally, the observed interindividual variability was accompanied by specific gut microbiota changes with inulin in *hum-ob* mice.

In two groups of mice (D2 and D3), inulin had no effect, whereas the two other groups (D1 and D4) responded with a positive impact of inulin, the metabolic improvement being more prominent in D1. The two groups of responders in mice received the gut microbiota from one diabetic donor (D1) and one prediabetic donor (D4), but mice receiving stools from another diabetic donor (D2) did not respond to inulin supplementation, suggesting that the diabetic status is not the main driver of the metabolic response to inulin. However, this hypothesis must be challenged in future intervention studies with a large number of patients with diabetes versus without diabetes. In D1 mice, FMT exacerbated the impact of HFD, and inulin counteracted the majority of these effects such as body weight and fat gain and hepatic and muscular lipid accumulation. Recent study demonstrated that the response of gut microbiota to resistant starch-containing dietary supplement differed depending on the initial gut microbiota from healthy donors used to inoculate mice. Interestingly, the gut microbiota from one diabetic donor (D1) and one prediabetic donor (D4) showed that obese *Akkermansia* spp and *Faecalibacterium* spp was not lower in the D1 cohort, the baseline level of *Akkermansia* spp was also decreased in *Bifidobacterium* and increased *Bifidobacterium* genera. In conventional mice fed a HFD, prebiotic treatment led to an increase in *Bifidobacterium* spp associated with a decrease in *Bilophila*. Vanderputte et al also demonstrated that inulin selectively increases *Bifidobacterium* and decreased *Bilophila* in mildly constipated individuals, an effect linked to improved constipation-related quality of life. Our data support that, in humanised mice, the changes of those bacteria is important to get interesting health effects, even beyond the context of obesity. Interestingly, the strong effect of inulin in D1 mice was also observed for the donor 1 during the intervention. Even if it is clear that the increase of physical activity by donor 1 could improve metabolic parameters during the intervention, the *hum-ob* mice model supports that the gut microbiota from this donor is favourable for metabolic response to inulin.

In D4 mice, even if FMT did not aggravate the impact of HFD, inulin improved fat mass and hepatic steatosis. In this group, inulin preferentially decreased bacteria positively correlated with detrimental metabolic features. Among them, inulin decreased *Bilophila* and *Barnesiella* and increased *Bifidobacterium* genera. In our study, we could recapitulate the importance of the selective changes in microbiota to explain the metabolic response to inulin (online supplementary figure 4). In D1 group, inulin preferentially decreased bacteria positively correlated with detrimental metabolic features. Among them, inulin decreased *Bilophila* and *Barnesiella* and increased *Bifidobacterium* genera. In conventional mice fed a HFD, prebiotic treatment led to an increase in *Bifidobacterium* spp associated with a decrease in *Bilophila*. Vanderputte et al also demonstrated that inulin selectively increases *Bifidobacterium* and decreased *Bilophila* in mildly constipated individuals, an effect linked to improved constipation-related quality of life. Our data support that, in humanised mice, the changes of those bacteria is important to get interesting health effects, even beyond the context of obesity. Interestingly, the strong effect of inulin in D1 mice was also observed for the donor 1 during the intervention. Even if it is clear that the increase of physical activity by donor 1 could improve metabolic parameters during the intervention, the *hum-ob* mice model supports that the gut microbiota from this donor is favourable for metabolic response to inulin.

In D4 mice, even if FMT did not aggravate the impact of HFD, inulin improved fat mass and hepatic steatosis. In this group, inulin preferentially upregulated bacteria known to be associated with beneficial effects on host metabolism, such as *A. muciniphila*, which negatively correlated with fatty liver in our study. In agreement, it has been shown that *Akkermansia* administration prevents the development of obesity and reverses hepatic and muscular lipid accumulation. Recent study demonstrated that the response of gut microbiota to resistant starch-containing dietary supplement differed depending on the initial gut microbiota from healthy donors used to inoculate mice. Interestingly, the gut microbiota from one diabetic donor (D1) and one prediabetic donor (D4) showed that obese *Akkermansia* spp and *Faecalibacterium* spp was not lower in the D1 cohort, the baseline level of *Akkermansia* spp was also decreased in *Bifidobacterium* and increased *Bifidobacterium* genera. In our study, the richness chaol index was similar at baseline and inulin did not modify it neither in *hum-ob* mice, nor in the human cohort. Previous studies suggested an inverse correlation between the initial faecal bifidobacterial numbers and the magnitude of increase of bifidobacteria with inulin or oligofructose-enriched inulin in healthy humans. Suggesting that inulin might induce a greater metabolic response in individuals with lower bifidobacteria at baseline. In our human cohort, the baseline level of *Bifidobacterium* spp was not lower in responders. Actually, only three genera were significantly different at baseline between responders and non-responders (*Anaerostipes, Akkermansia and Butyricicoccus*), even if other bacteria at baseline seem to drive the separation between both groups (PLS-DA analysis). We believe that the magnitude of response could be influenced by a subset of bacteria (rather than one specific bacterium) simultaneously affected by prebiotics. Consistent with this, Zhao et al demonstrated that a set of short-chain fatty acid (SCFA)-producing bacteria was promoted by dietary fibres and was key to improve host glycaemic control. They identified 15 strains of SCFA producers, belonging to *Faecalibacterium, Lactobacillus, Bifidobacterium* or *Ruminococcus* genera, which were suggested to exert beneficial effects on the one hand and keep detrimental bacteria away on the other. Accordingly, we found increased *F. prausnitzii*, *Lactobacillus* spp and *Bifidobacterium* genus in one group of responder mice.

The current data highlight that specificities of the gut microbiota drive the metabolic and microbial response to inulin. Choosing a specific nutritional strategy to manage non-alcoholic fatty liver disease, glucose homeostasis or adiposity would require to pay more attention not only on the initial gut microbiota but also on the potency of the gut microbiota to be modified adequately by specific prebiotics. In our study, the patient D4 met all the 'microbial criteria' to respond to inulin intervention but it was unsuccessful for this patient, because...
he did not follow dietary and behavioural advices. The consequence was an increase in body weight and fat mass, which could counteract the potential beneficial effect of inulin on metabolic disorders.

This means that a successful dietary intervention, namely with prebiotics, has to be considered as one of the tools to improve metabolic health but patient’s motivation remains crucial. One limitation of our study could be that all human donors were women, whereas the transplantation of the faecal material was performed in male mice only. This was motivated by the fact that all previous experiments testing inulin in HFD mice had been performed in male mice that are more prone to develop metabolic disorders than the female ones.40 41 In addition, no difference was observed in terms of improvement of BMI on inulin treatment following the gender in the human cohort (data not shown).

In conclusion, a personalised approach should be developed for prebiotic interventions to target obese patients prone to have a favourable response and to avoid discouraging negative outcomes. The identification of bacterial consortia within this complex ecosystem that drive the metabolic response towards prebiotics is of particular interest to implement adequate nutritional advices for personalised management of metabolic disorders in obesity.

Acknowledgements
We thank Remi Selleslagh, Véronique Allaeys, Isabelle Blave and Bouazza Es Saadi for their precious implication in the study. We thank the UCLouvain’s platform “Support en méthodologie et calcul statistique” and more specifically Céline Bugli and Lienven Desmet for their helpful advice concerning statistical analyses. We also thank Coralie Fenray, Marie Barea and Marjorie Fadue, the dieticians involved in the clinical trial.

Contributors
JR and NMD conceived and designed the experiments, interpreted the data and wrote the manuscript. JR performed the experiments and data analysis. AMN and LBB participated to design and to experiments. TLR designed the FMT protocol. JR, SH, BDP, MAG, MC, NF, NL and J-PT participated to the acquisition of the clinical data. AMN, TLR, SAP, QL and LBB participated to the analysis and interpretation of data. AMN, PDC, MC, NP, NL, J-PT and LBB provided intellectual input on the paper and reviewed the paper. NMD supervised the overall project.

Funding
This research is supported by the competitive cluster Wagrallim from Wallonia (FOOD4GUT 518 project, convention 1318148). NMD is a recipient of grants from Wallonia (FOOD4GUT project; 519 FiberTag project from European Joint Programming Initiative ‘A Healthy diet for a Healthy 520 Life’) and from Belgian National Scientific Research Fund (FRS-FNRS; convention PDR 521 1.0068.19). PDC is a senior research associate at FRS-FNRS (Fonds de la Recherche Scientifique), Belgium, and supported by the Funds Ballot Latour (Grant for Medical Research 523 2015). TLR is a postdoc fellow funded by FRS-WELBIO (WELBIO-CR-2017C-02).

Competing interests
None declared.

Patient consent for publication
Not required.

Ethics approval
Trial registered at ClinicalTrials.gov as NCT03852069 was approved by the ‘Comité d’éthique Hospitalo-facultaire de Saint-Luc’.

Provenance and peer review
Not commissioned; externally peer reviewed.

Data availability statement
For the gut microbiota analysis, raw sequences can be accessed in Sequence Read Archive database (SRA accession numbers PRJNA594535, PRJNA595549).
