Sphingomyelin synthase 1 mediates hepatocyte pyroptosis to trigger non-alcoholic steatohepatitis

Eun Hee Koh, Ji Eun Yoon, Myoung Seok Ko, Jaechan Leem, Ji-Young Yun, Chung Hwan Hong, Yun Kyung Cho, Seung Eun Lee, Jung Eun Jang, Ji Yeon Baek, Hyun Ju Yoo, Su Jung Kim, Chang Ohk Sung, Joon Seo Lim, Won-Il Jeong, Sung Hoon Back, In-Jeoung Baek, Sandra Torres, Estel Solsona-Vilarrasa, Laura Conde de la Rosa, Carmen Garcia-Ruiz, Ariel E Feldstein, Jose C Fernandez-Checa, and Ki-Up Lee

ABSTRACT

Objective Lipotoxic hepatocyte injury is a primary event in non-alcoholic steatohepatitis (NASH), but the mechanisms of lipotoxicity are not fully defined. Sphingolipids and free cholesterol (FC) mediate hepatocyte injury, but their link in NASH has not been explored. We examined the role of free cholesterol and sphingomyelin synthases (SMSs) that generate sphingomyelin (SM) and diacylglycerol (DAG) in hepatocyte pyroptosis, a specific form of programmed cell death associated with inflammasome activation, and NASH.

Design Wild-type C57BL/6J mice were fed a high fat and high cholesterol diet (HFHCD) to induce NASH. Hepatic SMS1 and SMS2 expressions were examined in various mouse models including HFHCD-fed mice and patients with NASH. Pyroptosis was estimated by the generation of the gaddermin-D N-terminal fragment. NASH susceptibility and pyroptosis were examined following knockdown of SMS1, protein kinase Cδ (PKCδ), or the NLR family CARD domain-containing protein 4 (NLRC4).

Results HFHCD increased the hepatic levels of SM and DAG while decreasing the level of phosphatidylcholine. Hepatic expression of Sms1 but not Sms2 was higher in mouse models and patients with NASH. FC in hepatocytes induced Sms1 expression, and Sms1 knockdown prevented HFHCD-induced NASH. DAG produced by SMS1 activated PKCδ and NLRC4 inflammasome to induce hepatocyte pyroptosis. Depletion of Nlrc4 prevented hepatocyte pyroptosis and the development of NASH. Conditioned media from pyroptotic hepatocytes activated the NOD-like receptor family pyrin domain containing 3 inflammasome (NLRP3) in Kupffer cells, but Wnt3 knockout mice were not protected against HFHCD-induced hepatocyte pyroptosis.

Conclusion SMS1 mediates hepatocyte pyroptosis through a novel DAG-PKCδ-NLRC4 axis and holds promise as a therapeutic target for NASH.

INTRODUCTION

Non-alcoholic steatohepatitis (NASH), an advanced stage of non-alcoholic fatty liver disease, is an important cause of morbidity and mortality worldwide and a leading cause of end-stage liver disease. Despite recent progress, the mechanisms involved in the transition from hepatic steatosis to NASH remain elusive. Lipotoxic injury of hepatocytes may be a primary event in the development of NASH and can contribute to inflammation, leading to hepatic fibrosis. However, the nature and mechanisms of lipotoxicity in NASH are not fully understood.

Apoptosis is a non-lytic form of death mediated by caspases and confers minimal effects on nearby cells. In contrast, programmed necrotic cell death (ie, necroptosis and pyroptosis) releases immunostimulatory intracellular components due to the rupture of cell membranes and induce inflammation.
Necroptosis is activated by the necrosis, which consists of the kinases receptor-interacting serine/threonine-protein kinase (RIPK) 1 and RIPK3 and the pseudokinase mixed linkage kinase domain-like protein (MLKL), and is known to occur in human and experimental NASH. Pyroptosis occurs predominantly in professional phagocytes—macrophages, monocytes and dendritic cells—and plays a major role in the clearance of bacteria from these cells. Moreover, pyroptosis has also been described in hepatocytes. Gasdermin-D and its N-terminal fragment (GSDMD-N) is a key player in pyroptotic cell death, whose levels increase in human and experimental NASH. Pyroptosis is initiated by either caspase-1 or caspase-11. Caspase-1 is activated by several inflammasomes, including the NOD-like receptor family pyrin domain containing 3 (NLRP3) inflammasome, which results in pyroptosis and the maturation and secretion of proinflammatory cytokines such as interleukin-1β (IL-1β) and IL-18. In the liver, NLRP3 inflammasome is prominently expressed in hepatic macrophages (Kupffer cells) with moderate expression in hepatic stellate cells (HSCs), and IL-1β produced by NLRP3 inflammasome promotes the proliferation and transdifferentiation of HSCs to induce liver fibrosis. Interestingly, knock-in mice with global or myeloid-specific Nlrp3 overexpression underwent caspase-1-dependent hepatocyte pyroptosis, liver inflammation and fibrosis. However, the role of NLRP3 inflammasome activation in hepatocyte pyroptosis is yet to be elucidated. NLR family CARD domain-containing protein 4 (NLRC4) inflammasome, which senses bacterial flagellin and the components of bacterial secretion, has been shown to cause macrophage pyroptosis and is activated by protein kinase C (PKC) δ. Moreover, NLRC4 inflammasome activation has been described in obesity-associated breast cancer progression and diabetic nephropathy. Yet, the specific role of NLRC4 inflammasome in NASH remains largely unknown.

Sphingolipids are ubiquitous building blocks of eukaryotic cell membranes that regulate a wide range of cellular processes including immunity, inflammation and metabolic diseases. In the liver, increased intracellular ceramide, the prototype sphingolipid and the precursor of complex sphingolipids, induces lipotoxic hepatocellular cell death by multiple mechanisms. Although ceramide can be generated by de novo synthesis in the endoplasmic reticulum from palmitoyl-CoA and serine or sphingomyelin (SM) hydrolysis by sphingomyelinases (Sases), ceramide can also be converted to SM and diacylglycerol (DAG) by sphingomyelin synthases (Sms). DAG produced by Sms can activate PKC, which in turn phosphorylates and activates a wide range of targets.

In this study, we investigated the role of Sms1, an enzyme that links de novo synthesised ceramide to SM synthesis and DAG generation, in hepatocyte pyroptosis and the pathogenesis of NASH. Our study identifies Sms1 as a novel player in the hepatocyte pyroptosis in NASH via the DAG-PKCδ-NLRC4 axis and delineates a previously unrecognised role of NLRC4 inflammasome in metabolic liver disease.

**EXPERIMENTAL PROCEDURES**
The detailed methods are provided in online supplemental data.

**RESULTS**

**Sms1 expression is increased in the livers of HFHCD-fed mice**

Cholesterol has emerged as the key player in NASH development through multiple pathological mechanisms, including the trafficking of free cholesterol (FC) to mitochondria. Moreover, hepatic FC has been shown to accumulate in obese diabetic mice and patients with NASH, and pharmacological lowering of cholesterol reversed NASH in obese, diabetic mice with metabolic syndrome. However, the link between cholesterol and sphingolipid metabolism in NASH has not been explored. Thus, we tested this possibility using a dietary cholesterol-driven murine model of NASH.

Feeding male C57BL/6 mice with high fat, high cholesterol (2.5%) diet (HFD) for 12 weeks induced NASH, whereas mice fed a high fat diet (HFD) developed simple steatosis without significant inflammation and fibrosis (figure 1A). Terminal deoxynucleotidyl transferase-mediated dUTP nick-end labelling (TUNEL) staining showed that apoptosis is evident in HFD-fed mice but not in HFD-fed mice (figure 1B). HFD feeding significantly increased the expression of serum palmitoyltransferase subunit 2 (Spt2), a key player in sphingolipid biosynthesis (figure 1C). HFD feeding significantly increased the levels of ceramide, SM and DAG and decreased the level of phosphatidylcholine (PC) (figure 1D and online supplemental figure S1).

As Sms1 use ceramide and PC as substrates to produce SM and DAG (figure 1E), we hypothesised that increased SM and DAG levels with a concomitant decrease in PC may reflect an increased expression in the Sms1. Feeding mice HFD significantly increased the hepatic expression of Sms1 but not Sms2 (figure 1F and online supplemental figure S2A). In contrast, HFD feeding increased the hepatic expression of Sms2, but had no effect on the expression of Spt2 and Sms1 (figure 1G, H and online supplemental figure S2B). Collectively, these findings show that HFD feeding upregulates the expression of Sms1.

**FC induces Sms1 expression**

We next examined the expression of hepatic Sms1 in other models of NASH induced by the methionine and choline-deficient diet (MCDD) and Western diet (enriched with fat, cholesterol and fructose). TUNEL staining showed increased hepatocellular apoptosis in MCDD and Western diet-fed mice (figure 2A).

Administration of MCDD and Western diet significantly increased the expression of Sms1, similar to HFD feeding (figure 2B, C and online supplemental figure S2C, D), suggesting that Sms1 induction is a characteristic feature of NASH independent of obesity. Intriguingly, Western diet also increased the expression of Sms2 (figure 2C). In addition, samples from patients with NASH/cirrhosis undergoing liver transplantation exhibited a higher expression of Sms1 but not Sms2 (figure 2D), and this result was also reflected at the protein level (online supplemental figure S2E). There was a trend for a relationship between Sms1 expression and the hepatic FC levels in the NASH/cirrhosis group, with a weaker correlation with body mass index (data not shown). Moreover, the expression of Sms1 did not change in liver specimens from subjects with steatosis (figure 2D). Thus, these findings suggest that higher hepatic Sms1 expression may be a common feature of NASH. Although previous studies and our findings in mice fed HFD (figure 1H) showed that Sms2 is associated with hepatic steatosis, Sms2 expression did not significantly change in the subjects with steatosis (figure 2D). Its relevance in human steatosis should be confirmed by using a larger cohort of subjects.

Cholesterol and SM are coenriched in the same membrane domains, and their molar ratio is tightly regulated to maintain membrane properties and signalling pathways. We thus examined whether increased FC levels induce the expression

As seen, the levels of hepatic FC were increased in mice fed HFHCD, MCDD or Western diet, but not in those fed HFD (figure 2E). To further test the direct link between hepatic FC and SMS1 expression, we used two different approaches. First, we fed mice a cholesterol-enriched diet (CED) supplemented with sodium cholate to sustain hepatic FC, which increased hepatic Sms1 expression but not Sms2 (figure 2F). In addition, treatment of AML12 hepatocytes with water-soluble cholesterol and Avasimibe, an acyl-CoA cholesterol acyltransferase inhibitor that maintains cholesterol in its unesterified form, significantly increased Sms1 expression (figure 2G). Moreover, Sms1 promoter activity significantly increased by cholesterol and Avasimibe, suggesting that FC induces the upregulation of Sms1 at the transcriptional level (figure 2H). Taken together, these results suggest that the accumulation of FC stimulates the transcriptional expression of Sms1 in NASH.

**SMS1 knockdown prevents NASH development**

To further elucidate the role of SMS1 in NASH, we examined the effect of shRNA-mediated knockdown of Sms1 in...

HFHCD-fed mice. 

Sms1 knockdown ameliorated HFHCD-induced liver inflammation and fibrosis (figure 3A, B), lowered expression of monocyte chemoattractant protein-1 (Mcp-1), tumour necrosis factor-α (Tnf-α), transforming growth factor-β1 (Tgf-β1), α-smooth muscle actin (α-Sma) and collagen type III α1 (Col3a1) (figure 3C and online supplemental figure S3A). Furthermore, HFHCD-induced increase in α-SMA immunoreactivity was decreased following Sms1 knockdown (online supplemental figure S3A), with similar findings observed for F4/80 immunohistochemistry (figure 3D). Knockdown of Sms1 also decreased the level of serum alanine aminotransferase (ALT) (figure 3E), but did not significantly change the hepatic triglyceride levels in HFHCD-fed mice (figure 3F). Hence, SMS1 mediates...

Data are presented as mean±SEM (n=5). *p< 0.01 and **p<0.001 vs control mice. #p<0.05, ##p<0.01 and ###p<0.001 vs shCon-HFHCD mice.

Diet-induced liver injury, inflammation and fibrosis, but not steatosis.

SMS1 mediates diet-induced hepatocyte pyroptosis

We next examined whether SMS1 mediates hepatocyte pyroptosis. Hepatocytes isolated from HFHCD-fed mice (HFHCD hepatocytes) exhibited increased SMS1 protein levels and enhanced release of lactate dehydrogenase (LDH) in the supernatant (figure 4A,B). Moreover, HFHCD hepatocytes had increased levels of GSDMD-N, a key player in pyroptotic cell death in NASH; however, the level of phosphorylation of MLKL, a marker of necroptosis, did not change (figure 4B). These data collectively indicate that pyroptosis specifically occurs in HFHCD hepatocytes. Importantly, knockdown of

Sms1 significantly decreased cell death as reflected by lower LDH release in the supernatant (figure 4C,D) and the generation of GSDMD-N in HFHCD hepatocytes (figure 4E). These findings support a causal link between SMS1 and HFHCD-induced hepatocyte pyroptosis.

DAMPs released from pyroptotic hepatocytes activate NLRP3 inflammasome in Kupffer cells in a SMS1-dependent manner
As damage-associated molecular pattern molecules (DAMPs) activate NLRP3 inflammasome,3,4 we examined the levels of DAMPs in HFHCD hepatocytes. The levels of ATP, high mobility group protein box 1 (HMGB1), and mitochondrial DNA (mtDNA) in the supernatants of pyroptotic HFHCD hepatocytes were significantly higher than those of control hepatocytes, and this effect was decreased on Sms1 knockdown (figure 4F). We then examined whether the DAMPs released from pyroptotic HFHCD hepatocytes activated NLRP3 inflammasome in Kupffer cells isolated from control mice pretreated with lipopolysaccharides (LPS) (figure 4G). As seen, the conditioned media from pyroptotic hepatocytes activated NLRP3 inflammasome in LPS-primed Kupffer cells, as evidenced by the increase in IL-1β levels (figure 4H) and this effect was suppressed on hepatic Sms1 depletion by shRNA treatment (figure 4H).

Plasma from mice and patients with NASH has been reported to contain high levels of extracellular vesicles (EVs) containing mtDNA and damaged organelles (ie, mitochondria) released from hepatocytes.16,17 Thus, we examined the presence of EVs from hepatocytes of HFHCD fed mice. As seen, the amount of mtDNA in the EVs was significantly increased in the supernatants of HFHCD hepatocytes and was significantly decreased by Sms1 depletion (online supplemental figure S4). These findings suggest that SMS1 plays a key role in the release of DAMPs that include mtDNA in the EVs from dying hepatocytes.

NLRC4-dependent pyroptosis in hepatocytes from NASH animals
The basal expression level of NLRC4 in hepatocytes is negligible compared with those in non-parenchymal cells and is minimally induced in cholestatic liver disease.16 Therefore, we first examined the expression of NLRC4 in hepatocytes from HFHCD-fed mice. As seen, the mRNA levels of NLRC4 were significantly higher in both isolated hepatocytes and liver extracts from HFHCD-fed mice, with similar findings observed for NLRP3 (online supplemental figure S5). The increased expression of both NLRP3 and NLRC4 in HFHCD-hepatocytes was also reflected at the protein level and in the phosphorylation of NLRC4 (figure 5A). Interestingly, Sms1 knockdown did not affect NLRP3 expression but abrogated the HFHCD-mediated NLRC4 phosphorylation (figure 5A). Moreover, knockdown of Nlrc4 did not significantly affect hepatic steatosis but prevented NASH (figure 5B,C and online supplemental figures S3B and S6) and significantly decreased g Asi cerm D activation reflected by the lower level of the GSDMD-N fragment and hepatocyte death (figure 5D,E). Furthermore, supernatant from hepatocytes of HFHCD-fed mice following Nlrc4 knockdown induced significantly lower production of IL-1β from LPS-pretreated Kupffer cells compared with hepatocytes from HFHCD-fed mice treated with control shRNA (figure 5F). As DAG is generated from SMS and is known to activate PKCδ, we explored the putative link between SMS1 and PKCδ activation. PKCδ phosphorylation was higher in hepatocytes from HFHCD-fed mice, but not in HFHCD-fed mice with Sms1 knockdown (figure 5G). Furthermore, knockdown of Pkcd in HFHCD-fed mice by shRNA prevented NASH (online supplemental figure S3C) and significantly decreased the phosphorylation of NLRC4 (figure 5H, I). These findings underscore a causal link between SMS1 and NLRC4 in inducing hepatocyte pyroptosis through PKCδ activation.

SMS1 overexpression induces hepatocyte pyroptosis
To further demonstrate that SMS1 contributes to NLRC4-mediated hepatocyte pyroptosis, we explored the role of SMS1 overexpression in hepatocyte pyroptosis. SMS1 overexpression into AML12 hepatocytes using lentiviral vectors induced phosphorylation of NLRC4 and activation of gasi cerm-D (online supplemental figure S7).

Caspase-1 but not Nlrp3 knockout mice are protected against hepatocyte pyroptosis
Considering the link between NLRP3 inflammasome and caspase-1 in liver inflammation and fibrosis,7 we investigated the role of the NLRP3-caspase-1 axis in HFHCD-induced NASH and hepatocyte pyroptosis by examining the susceptibility of Caspase-1 K/O or Nlrp3 K/O male mice (generated by the TALEN method in C57BL/6N mice).35 In line with previous findings,40,41 both Caspase-1 and Nlrp3 K/O mice were protected from HFHCD-induced hepatic inflammation and fibrosis (figure 6A, B). Moreover, hepatocytes obtained from HFHCD-fed Caspase-1 K/O mice were protected from pyroptosis (figure 6C, D). Interestingly, however, hepatocytes from HFHCD-fed Nlrp3 K/O mice showed an increased level of GSDMD activation (GSDMD-N fragment) and increased cell death, indicating that NLRP3 does not directly mediate hepatocyte pyroptosis (figure 6E, F). In line with these findings, conditioned media of hepatocytes from HFHCD-fed Caspase-1 K/O mice failed to induce IL-1β production in LPS-primed Kupffer cells from control mice (figure 6G). In contrast, conditioned media of hepatocytes from HFHCD-fed Nlrp3 K/O mice induced significant IL-1β production in LPS-primed Kupffer cells from control mice (figure 6H). These results suggest that caspase-1, but not NLRP3, is necessary for hepatocyte pyroptosis induced by HFHCD feeding.

Caspase-11 deletion fails to protect against hepatocyte pyroptosis or NASH development
In addition to caspase-1, caspase-11 can also induce pyroptosis by sensing cytoplasmic LPS.42 In contrast to Caspase-1 K/O mice, however, Caspase-11 K/O mice were not protected from HFHCD-induced NASH and hepatocyte pyroptosis (online supplemental figure S8), indicating that caspase-11 does not play a significant role in diet-induced NASH and hepatocyte pyroptosis. This outcome is in contrast with a recent finding that caspase-11 activated gasdermin-D in alcoholic hepatitis,43 but is consistent with the notion that caspase-1 but not caspase-11 is required for NLRC4-mediated pyroptosis in macrophages.44

DISCUSSION
Whereas apoptosis is a non-lytic form of cell death that confers minimal effects on nearby cells, it is recognised to play a role in the NASH. It was suggested that apoptotic cells can nonetheless release selective and low levels of DAMPs, thereby triggering inflammation in specific settings.45 Accordingly, we found that apoptosis was prominent in different models of diet-induced NASH but not in mice fed HFD, which induces steatosis but not NASH. In addition, we uncover a previously unrecongnised...

NAFLD and type 2 diabetes. We show that DAG produced was suggested as a key mechanism of hepatic insulin resistance, and that this phenomenon is downstream of PKCδ activation through SMS1 induction in hepatocytes. Previous studies showed that PKCδ was activated in the liver of MCDD-fed mice, but the responsible mechanism remained unknown. Our results suggest that DAG produced by SMS1 is responsible for the activation of PKCδ, as treatment with shRNA against Sms1 in HFFHCD-fed mice significantly decreased the phosphorylation of PKCδ. In addition, treatment with shRNA against Pkcδ and Nlrc4 decreased the phosphorylation of NLRC4 and hepatoctye pyroptosis, respectively, indicating that the SMS1-PKCy-NLRC4 axis is pivotal in hepatic pyroptosis during NASH. Importantly, Nlrp3 K/O mice were protected from NASH development, but hepatocytes from Nlrp3 K/O mice were still sensitive to diet-induced pyroptosis. These results show that NLRP3 does not have a significant role in hepatic pyroptosis, even though NLRP3 in Kupffer cells plays a crucial role in the progression of hepatic inflammation and fibrosis (figure 6b).

It should be noted that the content of cholesterol in the diet used to induce NASH in mice is higher than the recommended dose in humans. Since mice are resistant to maintaining FC levels, we fed mice with this specific HFHCD for 3 months to keep cholesterol in the free form. This outcome is similar to recent findings in mice fed with a lower cholesterol-enriched HFFHCD (0.2%) for 12–14 months. Thus, these findings indicate that feeding mice with a high CED for a short time (present study) is equivalent to feeding a moderate CED for longer periods, achieving with either approach a high level of FC in the liver. Of potential relevance, the increase in SMS1 expression in different NASH models in mice, including feeding the HFFHCD for 12 weeks, was observed in patients with NASH but not steatosis.

We found that SMS1, which is present in the Golgi and is involved in SM and DAG synthesis from de novo synthesised ceramide, plays a critical role in the pathogenesis of NASH in HFFHCD-fed mice. We also show that higher FC in hepatocytes is responsible for Sms1 induction at the transcriptional level. DAG was shown to induce insulin resistance in skeletal muscle and liver, and hepatic DAG activation of PKCy was suggested as a key mechanism of hepatic insulin resistance. NAFLD and type 2 diabetes. We show that DAG produced by SMS1 induces hepatoctye pyroptosis and NASH by sequentially activating the PKCδ-NLRC4 axis. Thus, DAG produced by different pathways may activate different isoforms of PKC that can induce either hepatic steatosis/insulin resistance (PKCy) or hepatoctye pyroptosis/NASH (PKCδ).

Based on the present findings, it could be speculated that inhibition of SMS1 may be of potential relevance to prevent or slow down NASH progression. Unfortunately, there are not characterised SMS1 inhibitors, whose identification would require extensive research. Alternatively, rather than inhibiting SMS1, which would be expected to result in decreased SM levels with potential adverse effects, it may be less problematic to antagonise SMS1 downstream targets. Further research is warranted in the future to identify potential targets of this new SMS1-DAG-PKCδ-NLRC4 axis in NASH.
